Contains—

Normal Flames for Photometric Use.—Dr. Schilling.—A series of figures.

Tar as Fuel in Gas-Works.—H. Raupp.—Illustrated with engravings.

Water Supply and Water-Works of the Town of Brunswick.—W. Claus.—A very complete description and review of this matter.

Brief Notes on the Water Supply and Water-Works of German Towns.—Dr. Schilling.

NOTES AND QUERIES.

Indigo-Carmine.—(Reply to "J. D. S.")—Consult the works mentioned in our issue of the March 11th last, under the heading "Colours and Pigments" (p. 120) and also Cooley's "Cyclopædia of Practical Receipts," published by Churchill.

Self-Raising Flour.—I should feel obliged if any one could give me information as to what material is introduced into flour to constitute it "self-raising." I have made a few rough analyses, but they have resulted in nothing. No carbonic anhydride is given off on treating the flour with water or with an acid.—B.Sc.

Lead Chromate.—(Reply to "Colourman.")—The following plan will best answer your purpose:—Take a solution of 33 parts of acetate of lead in 100 parts of water; precipitate this first by a solution of 22 parts of carbonate of soda in 60 parts of water, let the precipitate settle, and then decant the water. Next, add to the precipitate a solution of 17½ parts of neutral chromate of potassa in 50 parts of water; take care to stir this mixture well, and, after collecting on a filter, wash, press, and dry. The chromate thus prepared remains bright yellow, and does not redden by being ground up with water. The process is described at length in Dingler's *Polytechnisches Journal*, vol. lxxxvi, p. 438.

Fairfax's Test-Papers.—In justice to chemical students, I think the following points respecting "Fairfax's test-papers" should be made known:—(1) When placed in distilled water, the colouring matter is dissolved out in a few minutes, and leaves the paper so as to be totally unaffected by either acids or alkalis. (2) Sulphuretted hydrogen gas immediately decolourises it, indicating, according to the inventor's directions on the cover, a substance of an alkaline nature. The colour cannot be restored by acetic acid, but by one of the stronger acids, such as sulphuric. (3) The paper is apparently kept moist by chloride of calcium, the result being that the colouring matter stains anything with which the paper is placed in contact. These points scarcely bear out the announcement upon the cover—viz., that it is "the most delicate test for ordinary acids and alkalis," and "litmus superseded."—T. B.

MEETINGS FOR THE WEEK.

MONDAY, 30th.—London Institution, 4.

TUESDAY, 31st.—Institution of Civil Engineers, 8.

THE CHEMICAL NEWS.

VOL. XXI. No. 549.

ON THE PRESENCE OF POTASH IN CHROMATE OF LEAD.

By Dr. T. L. PHIPSON, F.C.S.,
Member of the Chemical Society of Paris.

ON making the analysis of some organic compounds recently introduced into the arts, it struck me that the carbon determinations obtained by oxide of copper were rather higher than those obtained by chromate of lead. The difference was slight, but nearly sufficient, in one case, to modify the formula deduced from the results.

It then occurred to me that this might be due to a small quantity of potash retained by the fused chromate of lead. I therefore acted upon some 500 grms. of this compound with boiling distilled water, and detected potash in the filtrate in every instance. The samples examined were prepared, I believe, in Germany. Four of them were tested quantitatively, and gave from 0.01 to 0.02 per cent of potash. Although so small, this amount of potash might, in some cases, influence the results of combustion, unless certain precautions are taken, as will be easily seen by taking into consideration the great weight of chromate of lead which enters the combustion-tube, and the small weight of matter usually subjected to combustion in order to ensure complete results.

Taking the most favourable view of the case, the quantity of matter burnt being stated at 0.100 grm., and the quantity of potash existing in the chromate of lead at 0.01 per cent, the quantity of chromate of lead which is used in the ordinary-sized combustion-tubes may be set down at 140 to 150 grms. Let us say only 100 grms. (for this quantity may be reduced to even less). In this case, we should have a certain loss of 1.2 per cent of carbon in the analysis.

The precautions to be taken to avoid error from this source are:—To use a slight excess of lead-salt in the preparation of the chromate, and to wash thoroughly with boiling water; to test occasionally for potash the chromate of lead supplied by commerce for the purpose of organic analysis; instead of 140 to 150 grms. of chromate in the combustion-tube, to take not more than 70 to 75, which may in most cases be easily done by using a narrower and rather shorter tube; and, finally, to take as large a quantity of the substance (0.2 to 0.5 grm.) as can be conveniently or safely taken for the analysis.

In these circumstances, chromate of lead will retain all its superiority over oxide of copper as an agent of combustion.

Analytical Laboratory, Putney, S.W.

EXPERIMENTS ON THE EFFECT OF ALCOHOL (ETHYLIC ALCOHOL) ON THE HUMAN BODY.*

By E. A. PARKES, M.D., &c.,
and
COUNT C. WOLLWICZ, M.D., &c.

THE authors, eminent army medical and scientific men, took the opportunity which the willingness and zeal of a very intelligent healthy soldier afforded them, of investigating the subject above alluded to, which, very rightly, they consider

of great importance for the precise knowledge of the physiological effects of alcohol on the human system. As might be expected, this paper describes, exhaustively and at great length, all the experiments made, and the conditions under which they were made. We can only give here a brief *résumé* of the general conclusions arrived at, from which we learn that small quantities of absolute alcohol (1 and 2 fluid ounces = respectively to 28.4 and 56.8 c.c.), given in divided doses to a perfectly healthy man, seemed to increase his appetite; 4 fluid ounces lessened it considerably, and larger quantities almost destroyed it. In other healthy persons, it may be different from the above; while, in most cases of disease, it seems probable that a much smaller amount of alcohol would destroy appetite. The number of beats of the heart in twenty-four hours (as calculated from eight observations made in fourteen hours) increases very largely—viz., an average of more than 13 per cent; while the actual work done by the heart in excess was found to be equal to lifting 15.8 tons 1 foot, and during the two last days of the experiment it did extra work, to the amount of 24 tons lifted as far. These few particulars, all belonging to physiology, may suffice to give a slight idea of the great merits of this paper, from which highly valuable conclusions may be drawn in respect of the use of, and far more the abuse of, ardent spirits. Although these were unknown as beverages some 200 years ago, they are now consumed to such an extent, that, for every man, woman, and child in Scotland, there is consumed annually 10 litres of alcohol, at 59 per cent of absolute alcohol, by bulk, chiefly in the shape of whisky.

ON A NEW APPARATUS FOR REDUCING CHLORIDE OF SILVER.*

By A. LEIBIUS, Ph.D.,
Assayer to the Sydney Branch of the Royal Mint.

In the refining of gold bullion by Miller's new chlorine process, the silver contained in the alloy thus treated is eliminated from the latter in the state of argentic chloride, which, by a subsequent process, is reduced to metallic silver.

This reduction has always been effected in the usual manner, viz., by placing the slabs of fused argentic chloride between plates of wrought-iron or zinc, with the addition of acidulated water. Although a perfect reduction to metallic silver has always been achieved, yet it required a considerable amount of time and manipulation, since the thick slabs of fused argentic chloride were, after two to three days, only partially converted into metallic silver, and had to be re-arranged in order to expedite their complete reduction. Such manipulations, however, were not only found to be very objectionable on account of the time they required, but more so on account of the very disagreeable work which they caused to the operator. The reduced spongy silver was broken up, by hand, into small pieces, in order to ascertain its complete reduction, and was then boiled in acidulated water to free it from iron or zinc.

It remained, therefore, a desideratum to effect the reduction of the fused masses of argentic chloride in a manner which would, at the same time, be quicker in its execution, and also obviate the just-alluded-to manipulations.

In 1868, Messrs. De la Rue and Hugo Müller, in London, constructed a galvanic battery, one pole of which consisted of fused argentic chloride the thickness of a goose-quill, the other pole of cylinders of zinc. Adopting this principle, I have endeavoured to construct an apparatus, which should fulfil the requirements before referred to.

* Abstract of a paper read before the Royal Society, May, 1870.

* Read before the Royal Society of Victoria.

After operating successfully with a small model which allows the reduction of about 250 ozs. of argentic chloride in one operation), I have, with slight modifications, constructed an apparatus which will reduce from 1400 to 1500 ozs. of argentic chloride in 24 hours. The apparatus and its dimensions are as follows:—

Two thick boards, 15 inches long, are joined together on both ends by three strong battens, so as to form an open box without a bottom, 13 inches long by 14 inches wide, and 15 inches high (inside measurement). The two boards forming the length of the box or frame contain seven vertical grooves, $\frac{1}{2}$ inch wide and $\frac{1}{2}$ inch deep, at intervals of $1\frac{1}{2}$ inches from each other. These grooves are cut down to a length of 12 inches, leaving 3 inches of each board forming the legs of the frame.

At the termination of these grooves passes horizontally a narrow slit, $\frac{1}{2}$ inch deep, and along the whole length of each board, into which a strip of metallic silver, $\frac{1}{2}$ inch wide and the thickness of about a threepenny-piece, is tightly fixed, projecting on one side of the frame about 18 inches beyond each board.

The seven grooves already alluded to are for holding zinc plates, $\frac{1}{2}$ inch thick, 14 inches long, and 12 inches high, which rest on both sides on the strips of silver, which, as just described, are jammed horizontally into the sides of the two boards. A connection is thus established between the seven zinc plates and these strips of silver.

The second part of the apparatus consists of a wooden frame, cut out of a solid board 1 inch thick, and supplied with two large iron handles. This frame is the same length as the box holding the zinc plates, but 3 inches narrower. It contains on each side, parallel to the direction of the zinc plates, twelve slits $\frac{1}{2}$ inch long, which hold silver bands $\frac{1}{2}$ inch broad and the thickness of a threepenny-piece. These silver bands are passed through the slits in the board, so as to form on each side of it six loops, $11\frac{1}{2}$ inches in length and $\frac{1}{2}$ inch wide. The six loops on one side are exactly opposite to those on the other side of the board, at a distance of about 9 inches. They are intended to hold the slabs of argentic chloride, which are 12 inches long, 10 inches high, and about $\frac{3}{4}$ inch thick, and are put through these loops lengthwise, projecting on each end about 1 inch beyond the silver bands.

The whole frame holds, as before stated, six of these slabs of argentic chloride, which are placed between the six spaces formed by the seven zinc plates, from which latter they are about $\frac{1}{2}$ inch apart on each side.

The projecting horizontal strips of silver jammed into the sides of the lower frame are then connected with the ends of the silver forming the loops in which the argentic chloride is suspended; and the whole apparatus thus charged is placed in a tub filled with water. After a short time, galvanic action is discernible; the liquid gets gradually warmer, and a strong galvanic current is observed. After about 24 hours, the action has nearly ceased, and the whole argentic chloride is found to be completely reduced to metallic silver, which retains in the silver loops the same shape, and, outwardly, also nearly the same appearance as when first introduced as argentic chloride. The latter contains always more or less chloride of copper (eliminated together with the silver during the operation of refining by chlorine), which is reduced together with the chloride of silver; in fact, this soluble chloride of copper helps to act as an exciting liquor for the battery. In the first experiments, a weak solution of salt (chloride of sodium) was used as exciting liquor; but it was found that this could be dispensed with, and only common water used (the action, however, is, in this case, a little retarded and does not become powerful until about two hours after the battery is set). By using a part of the resulting liquor from a previous reduction of argentic chloride, and which contains chloride of zinc, it has been found that the galvanic action sets in very rapidly, and accelerates thereby the completion of the reduction.

No acid is used; and, therefore, the amount of zinc used in each reduction has invariably been found to be almost the theoretical quantity required to combine the chlorine of the argentic chloride treated with the metallic zinc, in order to form chloride of zinc.

The quantity of metallic zinc thus used was always from 24 to 25 per cent of the weight of the argentic chloride reduced.

The reduced silver is boiled out in acidulated water, in order to remove the basic and oxy-chlorides, and finally in pure water, while still suspended in the silver loops. As soon as it is taken off the last boiling, it is immediately ready for the melting-pot, since the heat from the boiling water dries the porous mass of silver sufficiently to allow of its immediate melting. The seven zinc plates, when first used, weigh about 140 lbs. avoirdupois; the six slabs of argentic chloride, of the dimensions already given, weigh about 1400 ozs. troy.

The zinc plates are used over again, until too thin for that purpose, when they are re-melted, and cast into new plates. It has been found that the quantity of zinc used is little, if at all, increased by prolonging the time of connection with the silver plates after the reduction is completed; the whole apparatus, when once set in operation, can therefore be left to itself until it is found convenient to melt the reduced silver.

While this apparatus reduces the argentic chloride much quicker than if the latter is simply placed in contact with zinc or iron plates, it obviates any handling of the argentic chloride from the time the latter has been placed in the silver loops until the reduced silver is ready for the melting-pot;—advantages which have been fully appreciated by those who formerly had to resort to tedious and disagreeable manipulations.

ON THE SULPHO-ACIDS OF BENZOL.

By A. ROSS GARRICK,
Balyett, Stranraer, Scotland.

(Concluded from p. 245.)

SALTS OF ISOSULPHOBROM-BENZOLIC ACID.

Isosulphobrom-benzolate of Lead—

The lead-salt crystallises in small corny crystals. It contains three molecules crystal water, and is more readily soluble in water than the lead-salt of the former acid. It is prepared by neutralising a solution of the acid with lead carbonate.

Water estimation—0.4922 grm. of the salt dried in the air lost, at 110°, 0.0340 grm. = 6.90 per cent H_2O .

Lead estimation—0.4708 grm. of the dry salt gave 0.2120 grm. lead sulphate = 30.76 per cent Pb.

	Calculated.		Found.
$(C_6H_4BrSO_3)_2Pb$..	679	92.64	—
$3H_2O$	54	7.36	6.90
	733	100.00	
$(C_6H_4BrSO_3)_2$..	472	69.52	—
Pb	207	30.48	30.76
	679	100.00	

Isosulphobrom-benzolate of Zinc—

The zinc-salt, as prepared from the lead-salt by precipitating the lead exactly with a solution of zinc sulphate, forms very indistinct crystals easily soluble in water. It forms a marked contrast to the beautiful crystalline zinc-salt of the former acid.

Water estimation—(1) 0.1337 grm. of the salt dried in the air lost, at 110° , 0.0266 grm. = 16.82 per cent H_2O .
(2) 0.2395 grm. of the salt dried in the air lost, at 110° , 0.0397 grm. = 16.57 per cent H_2O .

Zinc estimation—0.1980 grm. of the dry salt gave, on ignition, 0.0306 grm. = 12.27 per cent Zn.

	Calculated.		Found.	
	I.	II.	I.	II.
$(\text{C}_6\text{H}_4\text{BrSO}_3)_2\text{Zn}$..	537.2	83.27		
$6\text{H}_2\text{O}$	108.0	16.73	16.82	16.57
	645.2	100.00		
$(\text{C}_6\text{H}_4\text{BrSO}_3)_2$..	472.0	87.89		
Zn	65.2	12.11	12.27	
	537.2	100.00		

Isosulphobrom-benzolate of Barium—

The barium-salt differs entirely from the barium-salt of the former acid. It crystallises in radiated fibres containing two molecules crystal water. The barium-salt of former acid forms splendid leaflets of a silver glance.

By neutralising a solution of the acid with barium carbonate, filtering, and evaporating, this salt is obtained.

Water estimation—0.3791 grm. of the salt dried in the air lost, at 110° , 0.0203 grm. = 5.32 per cent H_2O .

Barium estimation—0.3555 grm. of the dry salt gave, on ignition, 0.1358 grm. barium sulphate = 22.45 per cent Ba.

	Calculated.		Found.	
$(\text{C}_6\text{H}_4\text{BrSO}_3)_2\text{Ba}$..	609	94.39	—	
$2\text{H}_2\text{O}$	36	5.61	5.32

$(\text{C}_6\text{H}_4\text{BrSO}_3)_2$..	472	77.51	—	
Ba	137	22.49	22.45	
	609	100.00		

Isosulphobrom-benzolate of Calcium—

The calcium-salt forms small colourless crystals closely grouped together, which are easily soluble in water. It remains unchanged on exposure to the air, whereas the calcium-salt of the former acid is efflorescent and crystallises in large monoclinic prisms. It is prepared by neutralising a solution of the acid with calcium carbonate.

Water estimation—0.02365 grm. of the salt dried in the air lost, at 110° , 0.0088 grm. = 3.72 per cent H_2O .

Calcium estimation—0.2300 grm. of the dry salt gave 0.0602 grm. calcium sulphate = 7.65 per cent Ca.

	Calculated.		Found.	
$(\text{C}_6\text{H}_4\text{BrSO}_3)_2\text{Ca}$..	512	96.60	—	
H_2O	18	3.40	3.72	
	530	100.00

Ca	40	7.42	7.65	
	512	100.00		

Isosulphobrom-benzolate of Potassium—

The potassium-salt is exceedingly soluble in water. It crystallises in star-shaped groups containing water of crystallisation. The potassium-salt of the former acid forms large distinct rhombic plates, and is less soluble in water than this salt.

It is prepared from a solution of the barium-salt by precipitating the barium exactly with potassium sulphate.

Water estimation—0.2298 grm. of the salt dried in the air lost, at 110° , 0.0085 grm. = 3.69 per cent H_2O .

Potassium estimation—0.2620 grm. of the dry salt gave 0.0868 grm. potassium sulphate = 14.53 per cent K.

	Calculated.		Found.	
$\text{C}_6\text{H}_4\text{BrSO}_3\text{KO}$..	275.11	96.83	—

	275.11	100.00		

If we examine the characteristics of the two acids which, with their salts, have just been described, we cannot doubt but that we have to do with two entirely distinct bodies. Each salt of one acid differs very strikingly from the corresponding one of the other acid—no two analogous salts possess the least degree of resemblance with each other. In addition to this, the sulphobrom-benzolic acid first prepared is much less deliquescent than the following isomeric acid; the fusing-point could be with ease determined, and was found exactly at 88° . The isosulphobrom-benzolic acid, on the other hand, becomes liquid almost instantaneously on coming in contact with the air, so that all attempts at determining the fusing-point were entirely fruitless.

The physical properties compel us, then, to consider the two acids as isomeric, and not identical. Other means for characterising the two we do not possess, but circumstances cannot possibly work such differences in one and the same body as we observe between these two acids and the salts derived from them.

In the preparation of isosulphobrom-benzolic acid, after acting on sulphobenzolic acid with bromine in a sealed tube, the residue was dissolved in water and evaporated on the water-bath until freed from hydrobromic acid. On attempting to dissolve the residue, a substance separated, leaving the acid in solution. This was then separated by filtration, dissolved in alcohol, and, by allowing the solution to stand, needle-shaped crystals were obtained. It seemed probable that the crystals were those of tetrabrombenzol; and, on making an estimation of the amount of bromine, results were obtained agreeing pretty closely with the theoretical percentage of bromine contained in that compound. The small amount of substance at command rendered it impossible to make an estimation of the other constituents, or to control the estimation of bromine made.

Bromine estimation—0.1063 grm. of the substance gave 0.2007 grm. silver bromide = 80.33 per cent Br.

	Calculated for tetrabrombenzol, $\text{C}_6\text{H}_2\text{Br}_4$.		Found.

ON THE PREPARATION OF THE ISOMERIC DIATOMIC PHENOLS FROM THE SULPHO-ACIDS OF BENZOL.

The principal object of scientific chemistry at the present day is not the simple discovery of new chemical individuals. Although they are constantly appearing in all researches in the field of science, still they merely aid the investigator in simplifying, in systematising known facts. He accepts certain theories as a foundation for his researches; and, while he acknowledges the possibility that these accepted theories may be false, he nevertheless works on the assumption that they are true. If new facts brought forward by him present no points which speak against the theories, he has no right to disbelieve them—at

all events, not the right of experience. He must, on the contrary, if possible, show in what relation his researches stand to the ruling theories. If he then succeeds in proving the true position of but one substance, he has accomplished something towards the one grand end of the science—classification.

All the derivatives of benzol in which two hydrogen atoms are replaced by other univalent groups have been divided into three series, called, respectively, the ortho, para, and meta series. Of each derivative, there exists three isomeric varieties, corresponding to the three series. The difference between the three varieties arises from a difference in the arrangement in the substituting radicals in the molecule.

In consequence of characteristic reactions and methods of formation, the three isomeric diatomic phenols or hydroxyle derivatives of benzol have been placed as follows:—

Ortho series.	Para series.	Meta series.
Hydroquinone.	Resorcin.	Pyrocatechin.

We are, however, in possession of an elegant method for the formation of these phenols from the sulpho-acids. This is the method described by Kekulé, Würtz, and Dusart. It consists in fusing, at a high temperature, the potassium-salts of the sulpho-acids with potassium hydrate. By this means, the potassium hydrate acts upon the group SO_2HO , forming potassium sulphite and hydroxyle, which latter remains in the benzol molecule. The same thing takes place if one hydrogen is replaced by bromine or chlorine, with the difference, of course, that bromide or chloride of potassium are formed.

By applying this method to the acids above described, I have been enabled to show to which of the three groups they each belong.

Preparation of Resorcin, $\text{C}_6\text{H}_4\left\{\begin{smallmatrix} \text{HO} \\ \text{HO} \end{smallmatrix}\right\}$, from Disulphobenzolic Acid.

It was highly probable that, by adopting the method of Kekulé, Würtz, and Dusart, one of the three isomeric phenols (hydroquinone, resorcin, pyrocatechin) could be prepared from disulphobenzolic acid.

For this purpose, the potassium-salt of this acid was fused with three times its weight of potassium hydrate at a temperature of about 230° for two hours. The reaction proceeds as follows:—

The fused mass was then dissolved in water, acidified with dilute sulphuric acid, shaken up two or three times with ether, and the ethereal solution distilled on the water-bath. On concentrating the residue by evaporation, the solution separated out into distinct crystals. The crystals, which were of a dark colour, were allowed to stand over sulphuric acid, and then subjected to distillation, and the distillate collected between 270° and 280° .

The substance was subjected to analysis after standing for some time over sulphuric acid.

0.2662 grm. of the substance on combustion with cupric oxide, gave 0.6377 grm. carbonic acid = 65.32 per cent C.
0.2662 grm. gave 0.1365 grm. water = 5.69 per cent H.

	Calculated for $\text{C}_6\text{H}_4\text{O}_2$.	Found.
Carbon	65.45	65.32
Hydrogen	5.45	5.69
Oxygen	29.10	—
	100.00	

These results correspond to the formula $\text{C}_6\text{H}_4\text{O}_2$.

The substance, even in the pure condition, retained the smell of the phenols, and was soluble in water, alcohol, and ether. It melted exactly at 104° , which corresponds to the melting-point of resorcin given by Oppenheim and Vogt (*Ann. Chem. Pharm.*, Suppl., vol. vi., 376).

Its boiling-point agrees with that of resorcin, whereas

at the temperature at which it was distilled hydroquinone is not decomposed and pyrocatechin boils at 245° .

The fact that its solution became of a dark violet colour on the addition of a solution of ferric chloride, proved farther, without doubt, that the body so prepared was resorcin.

Adopting the method of Kekulé, Würtz, and Dusart, Oppenheim and Vogt (*Ann. Chem. Pharm.*, Suppl., vol. vi., p. 376) succeeded in preparing resorcin from sulphochlorbenzolic acid. For this purpose, they first prepared monochlorbenzol by the method recommended by Müller—viz., dissolving iodine in benzol, and for several hours conducting chlorine into the solution. The product was then subjected to fractional distillation, and the distillate collected from 130° to 140° . They then heated the monochlorbenzol so prepared with a little more than an equivalent of sulphuric acid. The crude acid was then dissolved in water, and freed from excess of sulphuric acid by treating it with barium carbonate. The barium was then precipitated with potassium carbonate, and the solution evaporated. The sulphochlorbenzolate of potassium so obtained was then fused with potassium hydrate in different proportions. In an experiment tried by fusing this salt with only a small proportion of potassium hydrate, dissolving the fused mass in water, neutralising with hydrochloric acid, and then shaking up with ether, they obtained a product containing chlorine.

By, however, employing a larger proportion of potassium hydrate, the red colour which was produced in the previous experiment was entirely destroyed; and, on neutralising the fused mass with hydrochloric acid, after dissolving the mass in water, and shaking up with ether, a solution was obtained free from chlorine. From this solution, they obtained, by spontaneous evaporation, crystals of a columnar or plate form, which were purified by subjecting them to distillation.

By analysis, they proved the substance to correspond to the formula of—

The crystals they describe as retaining the odour of phenol, having a sweet taste, and being soluble in water, alcohol, and ether.

The melting-point they found to be 104° , being 3° higher than the melting-point of resorcin as given by Hlasiwetz and Barth (*Ann. Chem. Pharm.*, vol. cxli., p. 224).

Preparation of Resorcin, $\text{C}_6\text{H}_4\text{O}_2 = \text{C}_6\text{H}_4\left\{\begin{smallmatrix} \text{HO} \\ \text{HO} \end{smallmatrix}\right\}$, from Sulphobrombenzolic Acid.

The fact that the sulphobrombenzolic acid was prepared in a manner analogous to that adopted in the preparation of the sulphochlorbenzolic acid, made it appear highly probable that it would also yield resorcin by applying the same method for introducing the hydroxyle groups.

Sulphobrombenzolate of potassium was accordingly fused with three times its weight of potassium hydrate at a temperature of about 275° for two hours. The reaction proceeds as follows:—

The fused mass was then dissolved in water, acidified with dilute sulphuric acid, and shaken up with ether. The ethereal solution was distilled on the water-bath, the residue concentrated by evaporation, and distilled. The substance so produced was exceedingly soluble in water, alcohol, and ether. On exposure to the air, it became rapidly of a reddish colour. The fact, also, that it became of a dark violet colour on the addition of a solution of ferric chloride furnished sufficient proof of the identity of the substance prepared with resorcin.

*Preparation of Hydroquinone, $C_6H_6O_2 = C_6H_4 \begin{Bmatrix} HO \\ HO \end{Bmatrix}$,
from Isosulphobrom-benzolic Acid.*

That in the same way one of the two remaining isomeric phenols (hydroquinone, pyrocatechin), could be prepared from isosulphobrom-benzolic acid, was in the highest degree probable.

Adopting the same method, isosulphobrom-benzolate of potassium was fused with three times its weight of potassium hydrate, at a temperature of about 275° , for two hours; the residue dissolved in water, acidified with dilute sulphuric acid and shaken up with ether. The ethereal solution was then distilled on the water-bath.

It now remained to be determined which of the two isomeric compounds was produced. Advantage was taken of the property of pyrocatechin to form, on the addition of lead acetate, a compound insoluble in water, whereas the hydroquinone remains in solution. By obtaining no precipitate on the addition of lead acetate, satisfactory proof was given of the absence of pyrocatechin. The solution was then decomposed with hydrosulphuric acid, filtered, and concentrated by evaporation on the water-bath.

On the addition of ferric chloride to a solution of the substance, a green precipitate was produced = quinhydrone, or green hydroquinone, $C_{12}H_{10}O_4$. On boiling this solution, this substance was decomposed, the characteristic odour of quinone was produced, and a brown material remained behind.

These reactions render it highly probable that by this process hydroquinone is produced. Certain it is that no pyrocatechin is produced, as this must have been precipitated by the addition of lead acetate to a solution containing it, whereas, as we have seen, no precipitate separated. Not a single reaction could give rise to a suspicion that the substance was resorcin. Unfortunately, the small quantity of substance at command did not suffice to answer the question, beyond a doubt, whether the substance produced was hydroquinone or not. As, however, the negative proof—viz., that it was neither pyrocatechin nor resorcin—is well established, we are justified in concluding that hydroquinone was produced.

As a result of these experiments, we can then draw the following conclusions:—

1st. In disulphobenzolic acid, sulphochlor-benzolic acid, and sulphobrom-benzolic acid, the substituting radicals have the same relative position to each other; and this is the same as that which exists between the hydroxyle groups in resorcin. This shows them to belong to the para series.

2nd. Isosulphobrom-benzolic acid belongs to the ortho series, the SO_2HO and Br standing to each other in the same relation that HO and HO stand to each other in hydroquinone.

Ortho series.	Para series.	Meta series.
Isosulphobrom-benzolic acid.	Sulphochlor-benzolic acid.	—
—	Sulphobrom-benzolic acid.	—
—	Disulphobenzolic acid.	—

A

LABORATORY OF EXPERIMENTAL RESEARCH.*

By Prof. ALBERT R. LEEDS.

ONE of the most important services rendered by the great Swedish chemist to his beloved science was that he freed it from its previously-attendant mystery and discomfort—its dirt and gloom. The cold outbuildings and damp stone floors, hitherto thought proper for destructive acids and noxious vapours and dangerous furnace-fires, were

* Communicated by Prof. Morton.

too unwholesome to be endured through the protracted severities of a Swedish winter; and so Berzelius carried his crucibles into comfortable rooms in his own dwelling, made the clumsy furnace yield to his convenient lamp, and made chemistry a science most cheerful and domestic. Among the young chemists who were attracted, by the splendour of his discoveries, to the home of Berzelius was Henry Rose. When, later in life, Rose became Professor of Chemistry in the University of Berlin, he also devoted two or three small rooms in his own house, and admitted to them a few students, who came, highly recommended for their skill and chemical knowledge, to work out analytical methods under his direction. Among them, and for several years his assistant, was Dr. Finkener, recently appointed Professor at the Berg Schule in Berlin. This Berg Schule occupies the Old Bourse, and the chemical laboratory is the large hall in which the bankers of Berlin were wont to assemble before their present magnificent Bourse upon the opposite side of the Spree was erected. The assiduity, care, and ingenuity which Dr. Finkener has displayed in the last, the sixth, and in former editions of Rose's great work on Analytical Chemistry, has given him a familiarity with analytical processes which has rendered him deservedly successful and popular as a teacher. To an American, the fees in the Institution appear incredibly small. For the daily use of the laboratory for five months, including gas, chemicals, and apparatus, the charge is 20 thalers (about 20 dollars in currency at the present time). Nor is this economy obtained at the sacrifice of those facilities which the student may reasonably expect in the present advanced state of chemical science. One or two agate mortars, a couple of steel mortars, the cork-borers, files, and other simple tools, the sand and water baths, &c., are the property and for the use of all. The students enforce the police regulations, and keep the laboratory in order. The apparatus for the evolution of sulphuretted hydrogen, carbonic acid, and hydrogen is arranged by an assistant; and the time of the student is not consumed in preparing these contrivances for himself: the same remark applies to the apparatus for the manufacture of chlorine, hydrofluoric acid, the determination of carbonic acid, nitrogen, &c.; to the burettes and standard solutions for volumetric analysis. In desk-room the student is limited, though not hampered for want of space. Of hood-room there is more than sufficient for all the evaporations and operations detrimental to health which the students are likely at any one time to be carrying on. How different from one of the largest of our American laboratories, where the regular charges are 100 dollars per term, and the incidental amount to a very considerable sum. Each student is required to consume time and money in constructing a sulphuretted hydrogen, carbonic, hydrogen, and other apparatus for himself; and, without he consumes more of both than most can afford, his apparatus, when completed, is inadequate to accomplish nice work or obtain accurate results. In respect to size and completeness, the laboratory of the Berg Schule at Berlin is much superior to that of the Mining School at Freiberg, now, and for many years past, under the direction of Professor Scheerer: the rooms are small, dark, and ill-provided with gas and apparatus.

Since the calamities which have fallen upon the kingdom of Saxony, the places of such as Breithaupt and his illustrious co-labourers have not been filled by men of equal renown; and the ancient glory of the Institution is departing. The student still goes to see the great cabinet of minerals accumulated by the father of Geology and his successor, and still may obtain excellent practical instruction in the determination of minerals. Here, as at some other places in Europe, and in our own country, where mineralogy is successfully taught, fragments of crystals are put into the hands of students, and they are expected, under the eye of the teacher, to determine their hardness, cleavage, and crystalline form. Their attention is directed to the peculiarities of surface condition, optical properties, &c.; and they are taught to substitute critical examination

for slovenly guess-work. The fiery enthusiasm with which the old Professor of Metallurgy performs his duties still attracts students, who have finished their studies at other schools, to Freiburg for this special course; and nothing certainly can be more gratifying than the zeal with which the lynx eyes of the Professor follow the assay from the incipient stages of its preparation, through the blazing furnace, to the triumphant moment when the button emerges into view. The metallurgical apartment at the Ecole des Mines in Paris is more imposing in appearance: with its practical working I am not so well acquainted. The Free Laboratory in the Jardin des Plantes is adapted only to elementary work; that at the Ecole Centrale is dirty and dismal; and that of the Sorbonne, which was erected at about the same time as the great Frederick Wilhelm Laboratories at Bonn and Berlin, is not comparable to either in size, elegance, and completeness. In the latter of these two noble edifices, the beautiful lecture-room is provided with a special laboratory for the preparation of lecture experiments, and also a museum of such minerals, apparatus, models, and metallurgical and industrial products as are useful in demonstration or illustration. Between the spacious apartments for qualitative and quantitative analysis, there is a room devoted to the preparation of reagents. There are also separate apartments set aside for metallurgic and pharmaceutical processes, weighing-rooms, a library, a room for organic analysis, and one for students engaged in original investigation.

There is no provision, however, for the prosecution of researches in physics, and but scanty accommodations to workers in physiology. Prof. Magnus, of the University of Berlin, has devoted a few rooms in his dwelling to physical research; and, while I was engaged there, three other students were present, one occupied by an investigation in acoustics, another in polarised light, and a third in the measurement of crystals of recently-discovered chemical compounds. A laboratory of physics is greatly needed at the present time in our own country. The teachers of natural philosophy in our colleges have little opportunity for fitting themselves by a course of special training for their duties, and are seldom able to make or improve their apparatus, or to enter with success into experimental research. A chemist is able to effect little who has not acquired, by years of practice, skill in the conduct of analyses. So, too, other things being equal, he will be the most successful physicist who is the best mechanician. In such an institution, the mechanical ought to advance with the mathematical education; and, while the pupil is studying mensuration, he might be mastering the turning-lathe; and, while applying calculus to optics, in grinding and mounting a lens. We do not advocate such an education only for those who design to be physicists by profession, but regard it as best adapted to develop many minds, and to bring forth a kind of talent eminently useful. Where shall the civil engineer, the miner, or the architect get such an education at present? Yet, to all these men, the ability to construct, as well as to plan a house, machine, or engine would be of inestimable value. Moreover, a long course of theoretical instruction alone is dry, and oftentimes disheartening, especially to those who, with great native ingenuity and mechanical skill, have little facility in mathematics. Such a physical laboratory should have a carpenter's shop, with tools for all kinds of joinery and turning; a machine-room, with furnace, bellows, anvils, vices, lathes, &c., and a room for finishing apparatus and the nicer kinds of work. Under the conduct of skilled mechanics, the students might be taught to make the apparatus requisite to demonstrate the principles of natural philosophy; and, when they were prepared to undertake researches of their own, or to take their degrees as engineers, they would be able to cope with the practical matters which would occupy their time and energies. Besides the workshops, there should be separate rooms in a laboratory of this description, devoted to researches in heat and optics, including spectrum analysis, photometry, micro-

scopy, and crystallography; to acoustics, electricity, and magnetism, and to the problems of engineering. We believe that there are many young men to whom an education of this kind would prove more attractive than any now obtainable, and that the practicable benefits, as well as the scientific results of such an institution would be very great.—*Journal of the Franklin Institute.*

ON THE CHEMICAL ACTIVITY OF NITRATES.*

By EDMUND J. MILLS, D.Sc.

IN the course of his researches upon nitro-compounds, the author found it extremely desirable to submit the genetic relations of those bodies to a detailed examination; in other words, to trace the modifications undergone by nitril as it is transmitted (from the chloride, hydrate, or free radical) through an adequate succession of combinations. One of the first steps in this direction is the preparation of nitrylic chloride, which can be most easily effected, according to a statement in Watts's "Dictionary of Chemistry,"† by the action of phosphoric oxychloride on plumbic nitrate—

Among other modes of verifying this equation, the examination of the residue left behind when excess of the oxychloride is heated with plumbic nitrate, and then distilled off in a current of dry air, appeared the most simple and obvious. The results were found not to agree with the equation; and after three nitrates had been tried, a law of chemical activity became evident, rendering the reaction worthy of pursuit for its own sake, although, as an available source of nitrylic chloride, it had failed entirely. The nature and mode of establishment of this law constitute the subjects of the author's memoir.

When a nitrate is treated with phosphoric oxychloride, as has just been mentioned, the residue contains phosphoric oxide and a metallic chloride. Within the limits of experimental error, or subject to other satisfactory explanation, the ratio between these two products is constant for each nitrate; and from that ratio a quotient α can be found as follows:—

$$\alpha = \frac{\text{weight of chlorine}}{\text{Cl}} \div \frac{\text{weight of phosphoric oxide}}{\text{P}_2\text{O}_5} = \frac{\text{weight of chlorine}}{\text{weight of phosphoric oxide}} \times 4.06$$

This quotient, which is different for each nitrate, is termed the "coefficient of chemical activity" of nitrates, and the method of obtaining it is designated the "method of ratios." The data from which α is deduced, namely, certain weights of argentic chloride and magnesian pyrophosphate, are, if singly considered, new with each experiment; they depend on time, rate of heating, the state of division of the nitrate, and other conditions. But, assuming the results to have been brought about under a law of chemical action, the values of α must be independent of those circumstances, by which the primitive numerator and denominator could have been only *pari passu* affected; they are related only to the actual occurrence of the reaction. This property, in a chemical ratio, has not, it is believed, been previously observed.

After describing the means employed for obtaining a current of dry air, the apparatus required for the reaction,

* Abstract of a paper read before the Royal Society, May 19, 1870.

† Vol. iv., p. 77.

and the individual experiments which were severally made, the following table of results is given, M being the symbolic value of a nitrate, and $Q = \frac{M}{a}$.

	a	M	Q
{ Thallous nitrate	8.76	265.30	30.29
{ Argentic nitrate	5.48	169.94	31.01
{ Plumbic nitrate	5.17	165.56	32.02
{ Rubidic nitrate	2.38	147.40	61.93
{ Cæsic nitrate	2.21	195.01	88.24
{ Potassic nitrate	1.99	101.14	50.82
{ Sodid nitrate	1.70	85.05	50.03
{ Lithic nitrate	1.61	69.00	42.86

The above list probably contains all the metallic nitrates that can be completely dried, excepting nitrates derived from amines and amides, which in the present state of our knowledge of the phosphamides, it was evidently advisable to exclude.

In the silver group, the mean value of Q is 31.11; and the following equation may be accepted therefor:—

$$a = \frac{M}{31.11}$$

In the potassium group we have likewise

$$a = \frac{M}{50.42}$$

Hence, within each set of nitrates, chemical activity is in direct proportion to symbolic value. It is further sufficiently apparent that (excepting subidic nitrate) a and M increase and diminish in the same general order. Within the limits of error, the Q column is an incomplete arithmetical series, the most probable value of whose first term is 6.258, so that

$$Q = m \cdot 6.258,$$

m being integral. Reasons are then adduced for identifying the number 6.25 with Dulong and Petit's constant of specific heat. Moreover, since the product of specific heat and symbolic value is, generally, $n \cdot 6.25$, and m is greater than n , taking $m = xn$ and s = the specific heat of a nitrate, we have

$$\begin{aligned} Q &= xn \cdot 6.25, \\ \text{but } M &= n \cdot 6.25; \\ \therefore Q &= xM, \end{aligned}$$

$$\text{and } a = \frac{M}{Q} = \frac{M}{xM} = \frac{1}{x}$$

the expression for chemical activity in terms of specific heat. Comparing the coefficients (a, a') for any two nitrates, the following relations are obtained:—

$$\frac{a}{a'} = \frac{m'}{m} \cdot \frac{M}{M'} = \frac{x' s'}{xs};$$

and it is shown that these formulæ agree sufficiently well with experiment. Where $m = m'$ and $x = x'$, we have the simple expression—

$$\frac{a}{a'} = \frac{M}{M'} = \frac{s'}{s}$$

The values of Q are strictly equivalent to each other in point of activity. The author believes that a is commensurate with the elective function of chemical attraction, first discovered by Bergman. He terminates the memoir with a reference to some well-known instances of chemical action (such as that of argentic nitrate on a mixture of aqueous potassic chloride, bromide, and iodide), as serving to bestow a presumptive generality on his principal conclusions.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Notes of a Course of Seven Lectures on Electrical Phenomena and Theories. By Professor TYNDALL, LL.D., F.R.S. (Lecture III.)

63. By the friction of a woollen cloth, amber is endowed with the power of attracting light bodies. This substance was called *Elektron* by the Greeks; hence the name Electricity was applied to the power of attraction exhibited by amber. This attraction remained an isolated fact for more than 2000 years.

64. In the year 1600, Dr. Gilbert, of Colchester, physician to Queen Elizabeth, showed that the power of attraction was shared by many other substances. Dry glass, for example, when rubbed by silk, and dry sealing-wax when rubbed by flannel, exhibit this attractive power: when they do so, they are said to be *electrified*.

65. An electrified body attracts and is attracted by all kinds of unelectrified matter; but *repulsion* may also come into play. Thus, rubbed glass *repels* rubbed glass, and rubbed sealing-wax *repels* rubbed sealing-wax; while rubbed glass attracts rubbed sealing-wax, and rubbed sealing-wax attracts rubbed glass.

66. Hence the notion of *two kinds* of electricity, one proper to vitreous bodies, and therefore called vitreous electricity; the other proper to resinous bodies, and therefore called resinous electricity.

67. These terms are improper, because, by employing suitable rubbers, we can obtain the electricity of sealing-wax from glass, and the electricity of glass from sealing-wax. We now use the term *positive* electricity to denote that developed on glass by the friction of silk; and *negative* electricity to denote that developed on sealing-wax by the friction of flannel.

68. Bodies endowed with the same electricity repel each other; while bodies endowed with opposite electricities attract each other. This is the fundamental law of electric action.

69. The rubber and the body rubbed are always endowed with opposite electricities. They always attract each other. The work done in overcoming this attraction appears as heat in the electric spark.

70. To find the kind of electricity with which a body is endowed, we must ascertain, by trial, the electricity by which the body is *repelled*; this, we may be sure, is the electricity of the body. Attraction does not furnish a safe test, because unelectrified bodies are attracted.

71. Some substances possess, in a very high degree, the capacity of transmitting the electric power, or condition; others possess, in a high degree, the capacity of intercepting it. The former bodies are called *conductors*, the latter bodies *insulators*.

72. The insulators were formerly called *electrics*, because they could be electrified by friction *when held in the hand*; the conductors were called *non-electrics*, because they could not be so electrified. The division is improper; because, if a conductor be insulated, it can readily be electrified. To keep it electrified, an insulator must be introduced between it and the earth.

73. What is electricity? Why should it adhere so tenaciously to some substances, and flow so freely through or along others? The human mind has made many attempts to imagine the inner cause of electric action, and it still continues to make such attempts. Formerly, it was thought that magnetism and electricity, as well as light and heat, were all the work of "imponderable matter," associated with the ordinary matter. In the case of light and heat, this conception has undergone profound modification, and we seem to see clearly the mechanical cause of both. But no similar clearness has as yet been attained with regard to electricity, though a strong presumption exists that our notions of it are destined soon to undergo a modification equally profound.

74. Meanwhile, we may employ the provisional conception furnished by the *theory of electric fluids*: it will enable us to classify our facts.

75. According to this theory, electrical attractions and repulsions arise from two invisible fluids, each self-repulsive, but both mutually attractive. The fluids are supposed to be mixed together, to form a compound neutral fluid in unelectrified bodies.

76. The act of electrification by friction consists in the forcible separation of the two fluids, one of which is diffused over the rubber, and the other over the body rubbed; but they may also be separated in another way, now to be illustrated.

77. If an electrified body be brought near an insulated, unelectrified conductor, but not into contact with it, the electrified body will decompose the compound fluid of the conductor, attracting one of its constituents and repelling the other. When the electrified body is withdrawn, the separated fluids re-unite and neutralise each other.

78. This forcible separation of the two fluids of a neutral conductor by the mere proximity of an electrified body is called *electric induction*. Bodies in this state are also said to be electrified by *influence*. Neutral bodies are attracted because they are first excited by induction.

79. When an insulated conductor is acted on by an electrified body, its repelled electricity is free, but its attracted electricity is held captive by the inducing electrified body. Connecting the conductor for a moment with the earth, its free electricity escapes; and then, on the removal of the electrified inducing body, the captive electricity is liberated, and diffused over the surface of the conductor.

80. Thus, by the mere proximity of the electrified body, and without establishing contact between it and the neutral conductor, we can charge the latter *with the opposite electricity*.

81. Two sheets of tin-foil (conductors) being separated from each other by a sheet of glass (an insulator), if one sheet have electricity imparted to it, it will act through the glass, and decompose the neutral electricity of the opposite sheet, attracting the one constituent and repelling the other.

82. If the second sheet be connected with the earth, the repelled electricity will flow away, and we shall have two mutually-attractive layers of electricity separated from each other by the glass.

83. If the one sheet of tin-foil be united with the other by a conductor, the two opposite electricities will flow together: the tin-foil is then said to be discharged. This discharge usually assumes the form of a spark.

84. If the surface of a cake of resin, or of a sheet of vulcanised india-rubber, be electrified, a plate of metal laid upon it will have its neutral fluid decomposed, its positive fluid being attracted and its negative repelled. On touching the metal plate, its free (repelled) electricity flows to the earth; and now, if the plate be raised by an insulating-handle, it will appear charged with positive electricity. This is the principle of the *Electrophorus*.

85. An electric machine consists of two parts; the insulator, which is excited by friction, and the prime conductor.

86. The first electric machine consisted of a ball of sulphur, which was rubbed against the hand. It was invented by Otto Von Guericke, Burgomaster of Magdeburg, in the year 1671. A sphere of glass was afterwards introduced, then a cylinder of glass, and finally a round glass plate, which was rubbed with dry silk.

87. The prime conductor is thus charged:—When the glass plate is turned by a handle, it passes between the silk rubbers, and is positively electrified. The electrified glass then acts by induction upon the prime conductor, attracting the negative electricity and repelling its positive. The conductor is furnished with points, from which the negative electricity streams out against the excited glass. Thus the prime conductor is charged, not by directly

communicating to it positive electricity, but by robbing it of its negative, the positive remaining behind.

88. The arrangement mentioned in Note 81 is virtually a Leyden-jar. Were the plate of glass there referred to moulded into the shape of a jar, one sheet of foil would cover its interior and the other its exterior. When the jar is connected with an electric machine, its charged interior coating acts by induction across the glass on the exterior coating, attracting the opposite and repelling the similar electricity.

89. In the experiment which led to the discovery of the Leyden-jar, the *hand of the experimentalist* served as the outer coating.

90. The escape of the repelled electricity of the outer coating to the earth leaves the captive electricity exposed solely to the attraction of that within the jar, and enables the jar to take a strong charge.

91. When the outer and the inner coatings are connected by a conductor, an *electric current* passes from the one to the other.

92. The current starts at the same instant from the inner and outer coatings, the *middle point* of the conductor being reached last by the current. This indicates that there are *two currents*, which start at the same moment from the inner and outer coatings.

93. It is agreed to call the direction in which the *positive electricity flows the direction of the current*.

94. When an electric current encounters resistance in its passage, heat is developed. This heat is sometimes so intense as to reduce metals to a state of vapour.

95. When a body is intensely electrified, it will discharge its electricity to an unelectrified body across an interval of air, in the form of an electric spark. Two bodies, oppositely electrified, discharge to each other in the same way.

96. When two oppositely-electrified clouds discharge towards each other, the track of the lightning marks the course of an electric current, and the sound of the thunder is the sound of an electric spark.

97. An electrified cloud, if it come near the earth, may discharge its electricity to the earth in the same way.

98. If the body through which the atmospheric electricity passes be a good conductor, and of sufficient size, no harm is done; but the *resistance* offered by trees, houses, and animals to the passage of the electricity usually causes their destruction.

99. The nervous system requires a certain interval of time to become conscious of pain. The time of an electric discharge is but a small fraction of this interval; hence, as a sentient apparatus, the nervous system is destroyed before consciousness can set in. If this be true (and there are the strongest grounds for believing it to be true), death from lightning must be painless.

100. When an electrified cloud passes over a pointed lightning-conductor, the opposite electricity of the earth is discharged from the point of the conductor against the cloud. The cloud is thus neutralised, and, in general, without producing thunder.

101. The duration of an electric spark amounts only to an extremely small fraction of a second. On this account, when moving bodies are suddenly illuminated by the spark from a Leyden-jar, they appear to *rest* for a short interval in the position which they occupied when the flash fell upon them. A moving cannon-ball, illuminated by a flash of lightning, appears to stand still for about one-eighth of a second, this being about the interval during which an impression, once made, persists upon the retina.

102. The unretarded electric spark will scatter gunpowder, but will not ignite it. To produce ignition, it is necessary to retard the discharge by sending it through a wet string.

103. If we double the quantity of electricity imparted to the same conductor, the density of the electricity is said to be doubled; if we treble the quantity, the density is said to be trebled, and so on:

104. On a *sphere*, the density of the electricity is the same at all points of its surface; on a *plate*, the density is greatest at the edges; and, on an elongated conductor, the density is greatest at the ends.

105. When the conductor ends in a sharp point, the electric density at the point is so great that the electricity discharges itself into the air.

106. The air thus electrified is self-repellent, and is also repelled by the point, the so-called "electric wind" being produced.

107. By causing an electric wind to issue from opposite points of a light body, the reaction of the two winds may make the body to float in stable equilibrium in the air.

108. The outer ends of two pieces of zinc and platinum, partially immersed in acidulated water, are in opposite electrical conditions. The free platinum-end shows positive electricity, while the free zinc-end shows negative electricity.

109. When both plates are united by a wire, the positive flows along the wire towards the negative, and the negative towards the positive; but, as mentioned in Note 93, it is agreed to call the direction in which the positive electricity flows the *direction of the current*.

110. The force which urges this current forward (the electromotive force) is enormously less than that which urges forward a current of frictional electricity. The consequence is that the latter is able to surmount resistances which are totally insurmountable by the former.

111. But, by linking cells together, we cause the voltaic current to approach more and more to the character of the frictional current. It requires, however, a battery of more than a thousand cells to make the current from a voltaic battery jump over an interval of air 1-1000th of an inch in length. An electric machine of moderate power, and furnished with a suitable conductor, is competent to urge its current across an interval ten thousand times as great as this.

112. The electric spark passes through air by the agency of the particles of the conductor from which it springs, and which are carried forward by the discharge.

113. But, measured by other standards, the frictional current is almost incomparably more feeble than the voltaic current: for example, it is not without special arrangements for multiplying the effect that the current from a large electrical machine is enabled to deflect a magnetic needle.

114. Faraday immersed two wires, the one of zinc and the other of platinum, each 1-13th of an inch in diameter, in a cell of acidulated water. The depth of immersion was only $\frac{1}{4}$ inch, and the time of immersion only 3-20ths of a second; still, he found that the electricity generated by this small apparatus, in this brief time, produced a distinctly greater effect upon a magnetic needle than twenty-eight turns of the large electric machine of the Royal Institution.

115. A cubic inch of air, if compressed with sufficient power, may be able to rupture a very rigid envelope; while a cubic yard of air, if not so compressed, may exert but a feeble pressure upon the surfaces which bound it. Now, the electricity of the machine is in a condition analogous to the compressed air; its density, or, as it is sometimes called, its intensity or tension, is great. The electricity from the voltaic battery, on the other hand, resembles the uncompressed air; it exceeds enormously, in *quantity*, that from the machine, but it falls enormously below it in *intensity*.

116. The deflection of a magnetic needle, and other actions of the voltaic current, depend solely upon *quantity*; hence the vast superiority of the voltaic current in producing such deflection.

117. Faraday found the quantity of electricity disengaged by the decomposition of a single grain of water in a voltaic cell (see Note 5) to be equal to that liberated in 800,000 discharges of the great Leyden battery of the Royal Institution: this, if concentrated in a single discharge, would be equal to a great flash of lightning. He

also estimated the quantity of electricity liberated by the chemical action of a single grain of water on 4 grains of zinc to be equal in quantity to that of a powerful thunder-storm.

118. Weber and Kohlrausch have found that the quantity of electricity associated with 1 milligramme of hydrogen in water, if diffused over a cloud 1000 metres above the earth, would exert, upon an equal quantity of the opposite electricity at the earth's surface, an attractive force of 2,268,000 kilogrammes.*

ROYAL IRISH ACADEMY.

At the last meeting of this Society, held at their House, PROFESSOR JELLETT in the chair, Dr. R. M'DONNELL, F.R.S., read a paper on "*A New Theory of Nervous Action as regards the Propagation of Sensation Along the Nerves.*"

The author's paper might be briefly described as an application of a theory similar to the wave theory of light to the propagation of sensation along the nerves. He compared this "undulatory" theory of nervous conduction with the hitherto more generally received hypothesis of distinct nerve-conductors, supposed to exist for each kind of sensation, pain, heat, tickling, &c.; and attempted to point out that the former is at once a simple hypothesis, and more in harmony with the ideas now prevalent as to the propagation of light, heat, electricity, &c.

The author also dwelt upon many points of analogy between the absorption or interception of waves of heat or of light and the somewhat similar phenomena as regards nerve-conduction where one kind of sensation is felt and another ceases to be any longer perceived, as in cases where the patient feels the contact of the hand, but cannot distinguish heat, or *vice versa*.

CORRESPONDENCE.

ANALYSIS OF WATER.

To the Editor of the Chemical News.

SIR,—In your last number Mr. Spiller has commented on Professor How's analyses of an acid water from the coal-field at Stellarton. He thinks he has detected "one or two anomalies in the paper, which seem to have escaped the attention of the author, as well as of the gentlemen composing the 'committee of publication' of the *Chemical Society's Journal*;" and the first of these is an unusual arrangement of the constituents by which the chlorides of potassium and sodium are made to exist in solution in the presence of free sulphuric acid. Now, in reading the paper as it passed through the press I did observe this; but it never entered into my mind that it was my duty to correct the author's arrangement, especially as I thought he had as good a right to adopt that arrangement as any other of the same kind. No doubt it would have been more in accordance with received tradition to join the sulphuric acid to the potassium on the old principle of the strongest base to the strongest acid; but this rule is little else than an Idol of the Theatre, and there is this awkwardness about its application to the case in question that we do not know which is the stronger base potassium or sodium, or which the stronger acid, sulphuric or hydrochloric. In fact, there must have been both acids in a free state in the well and pond, for it has been established—at least, I consider it so—that where compounds of several bases and acids come together in solution, each acid arranges itself in combination with

* The metre is a yard and one-eighth in length; the milligramme is 1-28000th of an ounce; the kilogramme is 2 lbs. 34 ozs.

each base in certain definite proportions dependent on the quantity of each of the constituents, and probably on the temperature: but what these proportions are in a colourless water no one can say; even the refractive index will scarcely help us.

It is true the results of these analyses might have been put down as so much calcium, magnesium, iron, potassium, sodium, and hydrogen, combined with so much chlorine, SO_4 , and SiO_2 , but neither the public nor chemists themselves are, perhaps, quite prepared for such a mode of representing the salts that exist in a water.

Should Mr. Spiller's letter, and this one, start a discussion as to the best method of recording the results of analysis in similar cases, they will do some good service.

How "a little alumina" got into the boilers is a question I shall leave for Professor How, if he chooses to explain it.

The third objection is of a totally different nature, and seems to arise from a misapprehension of Professor How's meaning. The statement that "the pond rests upon the measures immediately underlying the Acadia seam of coal" is intelligible enough if we remember what geologists mean by the term "underlying." If I am not misinformed these coal seams crop out at the surface, and that at a considerable angle; hence there is no difficulty in imagining a pond on the underlying coal measures in some place where the upper stratum has been removed either by the processes of nature or by the miner's art.—I am, &c.,

J. H. GLADSTONE.

May 30, 1870.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, May 23, 1870.

Leaving aside the papers and memoirs relating to pure and applied mathematics, and to natural history, this number contains the following original memoirs and communications relating to chemistry and collateral sciences:—

Action of Water upon Iron, and of Hydrogen upon Oxide of Iron.—H. Sainte Claire-Deville.—The author relates, at great length, a series of experiments which may be summarised as follows:—"Perfectly pure iron, kept at temperatures varying from 150° – 1600° , is treated with vapour of water of a known tension and temperature. Under these conditions, the following results are obtained, which prove that the decomposition of vapour of water by iron, while red-hot, is rigorously subject to all the laws which govern the tension of saturated vapours. The author states that, according to his experience, all changes of the state of aggregation must be strictly analogous, because the predominating phenomenon in all is the evolution or absorption of latent heat.

Fire-Clay made Stoves manufactured by MM. Muller and Co., Ceramic Manufacturers at Ivry.—General Morin.—The author states that the experiments made with these stoves at the Conservatoire des Arts et Métiers are highly satisfactory. The useful effect of heat given off by the fuel (coke) amounts to 0.93 per cent. The air in the rooms where these stoves were placed was not at all vitiated so as to incommode those present, notwithstanding the interior of the stoves (that part wherein the fuel is placed) became thoroughly red-hot. The author says that, taking all in all, these stoves, when suitably connected with flues, will afford a cheap, and, in every respect, wholesome mode of heating apartments.

On the Hail which Fell at Paris during a Thunderstorm on the 22nd of May last.—A. Trécul.—It appears that a heavy thunderstorm took place, accompanied by hailstones of extraordinary size (2 centims. by 1½) as well as shape (pyriform). A portion of most of them was, as usual, opaque; but a great many were partly opaque,

and partly transparent and crystalline, in a peculiar and (for water) very unusual shape. Dr. Chapelas states, in relation to the storm alluded to, that it stands, according to his observations, in a very intimate relation to the Aurora Borealis seen on the 20th of May, and then accompanied by peculiar perturbations of the instruments applied for meteorological observations.

Report on a Memoir written by Dr. Vétillard, "On the Vegetable Fibres Applied to Industrial Purposes."—Professor Chevreul.—This lengthy paper gives a brief outline of the extensive researches made on flax, hemp, cotton, jute (*Cochorus capularis*), China grass (*Urtica utilis*), and New Zealand flax (*Phormium tenax*). Owing to the importance of the contents of this paper, wherein very accurate and readily executed tests are given for the purpose of detecting the kind of various vegetable fibres, we intend to give a more extended account of the memoir at a future time.

On the System of the Mineral Lodes of the Hundsrück.—A. Vézian.

Compressibility of Gases under High Pressure.—L. Caillietet.—The author has studied the variation of compression of air and hydrogen between 1 and 800 atmospheres. Up to 80 atmospheres' pressure, air is more compressed than it should be if it followed the law of Mariotte; and at 680 atmospheres' pressure it only occupies two-thirds of the space which it ought to do theoretically. The method by which the author is enabled to measure the volumes occupied by a gas in an opaque apparatus is very simple. The glass tube is enclosed in an iron one, the former, containing the gas, is tightly filled. The mercury, which serves for the transmission of pressure, whitens the gold, leaving a well-defined mark on it after the pressure ceases.

Combinations of Protochloride of Platinum and Oxide of Carbon.—Dr. J. Schützenberger.—The author describes three new compounds, viz.:— COPtCl_2 , chloroplatinate of carbonyl, the most stable of these bodies, fusing at 194° ; $\text{C}_2\text{O}_2\text{PtCl}_2$, chloroplatinate of dicarbonyl, fuses at 142° ; $\text{C}_2\text{O}_2\text{Pt}_2\text{Cl}_4 = \text{COPtCl}_2 + \text{C}_2\text{O}_2\text{PtCl}_2$, a compound of one molecule of each of the preceding bodies, fusible at 130° . Water decomposes these substances instantaneously, platinum being set free and chlorhydric and carbonic acids formed, or, also, sometimes a mixture of carbonic acid and carbonic oxide. Alcohol also decomposes these substances.

Action of Acetylen upon Mixed Aceto-Hypochlorous Anhydride (Acetate of Chlorine).—M. Prudhomme.—The author describes, at length, a series of experiments, resulting in the discovery of a body—

that is to say, the aceto-chlorhydrine of a tetratomic alcohol.

Action of Sulphuric Anhydride upon the Protochloride and Sesquichloride of Carbon.—M. Prudhomme.—With the protochloride of carbon, C_2Cl_4 , anhydrous sulphuric acid yields, on being heated in a sealed tube to 150° , sulphurous acid and chloride of trichloroacetyl, $2(\text{C}_2\text{Cl}_4) + \text{S}_2\text{O}_5 = 2(\text{C}_2\text{Cl}_4\text{O}) + \text{S}_2\text{O}_3$; with the sesquichloride of carbon, $\text{C}_2\text{Cl}_4\text{C}_2$, the same body, and, in addition thereto, oxychloride of sulphur, $\text{S}_2\text{O}_3\text{C}_2\text{Cl}_4$, is obtained, $\text{C}_2\text{Cl}_4\text{C}_2 + \text{S}_2\text{O}_5 = \text{C}_2\text{Cl}_4\text{O} + \text{S}_2\text{O}_3\text{C}_2\text{Cl}_4$.

Observations on the Batswing-Burner Flame.—A. Baudrimont.—The chief point of interest is that the aforesaid flame consists of two distinct portions, one of which (the interior) has a comparatively low temperature, while it is surrounded by a luminous envelope, the temperature of which exceeds that of molten platinum. Indeed the author found that a platinum wire 1-roth m. thick, when properly placed in this flame, fused immediately.

Two Instances of Upheaving of the Soil recently noticed.—Dr. de Botella.—The author, writing from Madrid to M. Elie de Beaumont, states that the steeples of the villages of Bemfizes, and the entire village of Saldunde, have been considerably lifted up (upheaved), since 1847, in a direction nearly parallel to the system of the Saucorrois. The extreme distance between the upheaved points is 300 kilometres. The celebrated geologist to whom this communication is made said, at the meeting, that something similar was observed some years ago in the Kingdom of Wurtemberg, and that it is very probable that, if well conducted observations in this direction are set on foot, many such facts will come to be noticed.

Zeitschrift für Chemie von Beilstein, No. 8, 1870.

This number contains the following original papers, nearly all of which were read at the Imperial Russian Chemical Society, at the late meetings of that Society:—

Nitro Compounds.—A. Engelhardt and P. Latschinoff.—The chief object of this very lengthy paper is to prove that the so-called nitro-compounds, which are usually considered to be products of a metaleptic displacement of hydrogen by the nitro group NO_2 , so that the chemical functions of the bodies which undergo this substitution remain the same, are really so altered, as regards their properties and characters, as if the body in which the substitution took place was oxidised. The authors have made a lengthy series of experiments to prove their statement; and the paper is divided into the following sections:—Nitrophenols and benzols; action of pentachloride of phosphorus on ortho nitrophenol; phosphoric acid ortho-nitrophenol, $(\text{C}_6\text{H}_4(\text{NO}_2)_2)_3\text{PO}_4$; action of PCl_5 upon volatile nitrophenol; nitrochlorobenzols; nitrotrichlorobenzols; binitro-phenol and binitrochlorobenzol; binitro-bichlorobenzol; trinitro-phenol and trinitrochlorobenzol. The authors classify the nitro compounds of phenol

according to their behaviour with PCl_5 , and also according to the properties of their chloranhydrides and amides, in the following manner:—

	Chloranhydrides.	Amides.
Phenol.	Chlorobenzol.	Aniline.
Ortho-nitrophenol.	α Nitro-chlorobenzol.	β Nitraniline (Hoffmann's).
Volatile nitrophenol.	β Nitro-chlorobenzol.	Dinitro-aniline.
Dinitrophenol.	Dinitro-chlorobenzol.	Trinitro-aniline.
Trinitrophenol.	Trinitro-chlorobenzol.	

In this grouping, the acid character of each succeeding compound becomes stronger.

Butylen.—A. Butlerow.—The main gist of this paper is to establish the author's priority of certain researches made by him, and the correction of some errors committed by Dr. Markownikoff in his paper published in the Russian language on butylen.

Preparation of Trimethyl-Carbinol from Isobutyl-Alcohol.—A. Butlerow.—Isobutyl is first prepared by passing HI into boiling butylic alcohol. This substance is next employed for the preparation of butylen in the following manner:—4 parts of potassic alcohol (consisting of 1 part of KHO and 3 parts of alcohol 90 per cent), 1 part of solid caustic potassa, and 2 parts of isobutyl are mixed and gently heated. The butylen (a gas) is collected in a gas-holder, after having been washed with alcohol and water. The butylen is converted into trimethyl-carbinol by a complicated process, based upon the complete absorption of butylen by sulphuric acid (3 parts H_2SO_4 and 1 part H_2O), and its conversion thereby into a liquid which, after saturation with K_2CO_3 , and distillation, yields the compound in question.

On Isomeric Dibromotoluoils.—F. Wroblevsky.—The author's researches have been made with the view of obtaining compounds different from those obtained by Dr. Fittig by the direct action of bromine upon toluol. For this purpose, solid toluidine was brominated, and the product converted into azoperbromide, $\text{C}_6\text{H}_4\text{Br}_2\text{NBr}$, and this substance made the starting-point for the preparation, first, of dibromotoluoil, $\text{C}_6\text{H}_4\text{Br}_2\text{BrCH}_3$, a liquid not solidified even at -20° , boils at 239° , sp. gr. 1.812 (at 19°), soluble in alcohol, and yields, when nitrated, only one nitro-dibromotoluoil, $\text{C}_6\text{H}_3\text{NO}_2\text{Br}_2\text{BrCH}_3$, a solid crystalline substance fusing at 87° . The author further describes: Dibromonitroil; another dibromotoluoil, $\text{C}_6\text{H}_4\text{Br}_2\text{Br}$; dibromonitrotoluoil; dibromotoluidine; nitro α bromtoluoil; nitro σ bromtoluoil; and nitro- β iod- σ bromtoluoil.

Products of Decomposition of Glycogen by Sulphuric Acid.—Dr. A. Stscherbakoff.—After referring to Dr. Tichanowitsch's work on the origin of the hydrates of carbon within and without the animal organism, published in the Russian language, at Cherkow, the author describes a series of physiologic-chemical experiments, the main result of which is that the composition of glycogen is to be expressed by $\text{C}_{10}\text{H}_{15}\text{O}_{12}$.

Preliminary Notice on a New Valerianic Acid.—A. Butlerow.—The author states that he has succeeded in obtaining from trimethyl-carbinol a valerianic acid—

Explanation of the Action of Peroxide of Manganese upon Chlorate of Potassa in the Preparation of Oxygen.—Dr. G. Krebs.—The utility of mixing peroxide of manganese, for which, however, may be substituted substances such as peroxide of iron, oxides of zinc and tin, burnt gypsum and others, provided they are previously well dried (best by ignition) with chlorate of potassa, is based upon the fact that the substances alluded to, which are infusible by themselves, are the carriers and transferers of heat to the chlorate of potassa, each particle of which is surrounded with a source of heat, which aids its rapid decomposition. The peroxide of manganese is prevented from being itself decomposed, because the chlorate of potassa withdraws from it heat, for the purpose, first, of its own fusion, whereby heat becomes latent; secondly, by its decomposition. The author states that, when oxide of iron, or peroxide of manganese, are strongly heated in a crucible, and chlorate of potassa very gently fused at the same time, by itself, in a porcelain dish, the addition of the hot (not red-hot) oxides to the fused chlorate causes the evolution of oxygen to set in instantaneously, and with so great violence that, unless this experiment be performed in open vessels, and with small quantities at a time, serious explosions may occur.

American Journal of Pharmacy, May, 1870.

Leaving aside the bulk of those original papers which relate strictly to pharmacy, and which are very valuable, this number contains the following original papers relating to chemistry and collateral sciences:—

Pumpkin Seeds.—Benton G. Bosch.—The author's researches on this subject have proved that these seeds contain 75 per cent of an oily kernel and 25 per cent of husk. The oil, extracted by ether, resembles, in taste, olive oil. The kernel contains, moreover, an oleo resin, to which, the author believes, the efficacy of the drug is due; this principle he calls *cucurbitin*—it is an anthelmintic.

Active Principle of the Catalpa Bignonoides.—E. A. Rau.—The author has investigated the bark of this tree, rejecting the outer corky layer, by a process too lengthy to be described here. He found a crystalline substance, insoluble in water and dilute alcohol, best dissolved in ether and chloroform. This substance, also insoluble in dilute alkalis and acids, was found to be neutral and free from ash; the taste of this substance was found to be intensely nauseous and

bitter. The author also found a glucoside, a tasteless resin, and tannin.

Sulphate of Lime, an Impurity in Tincture of Chloride of Iron.—Dr. R. Battey.—The author records that the pharmaceutical preparation alluded to often deposits long, slender, delicate needles, along with a yellowish precipitate. On investigating these crystals, he found them to be sulphate of lime; but there is no necessary connection between that substance and the yellowish deposit, the nature of which is not further alluded to.

Light Sulphate of Quinine.—L. Strehl.—The author, writing from Chicago, U.S., reports that a small parcel of quinine was recently purchased there, labelled "light sulphate of quinine" manufactured by Lord, Bros., Ludgate Hill, London. That firm being unknown, the "quinine" was submitted to the ordinary tests for purity, and was discovered to exhibit a rhombic, prismatic, crystalline structure, taste bitter, entirely soluble in cold water, no indications of the presence of quinine with chlorine-water and ammonia, nor also with the former and ferrocyanide of potassium, and afterwards a few drops of ammonia. No sulphuric acid was detected, but, instead thereof, hydrochloric acid. All the reactions made confirmed the idea that, instead of the substance being sulphate of quinine, it was hydrochlorate of cinchonine. That salt resembles closely, in appearance, sulphate of quinine, and is a substitution which might readily pass unnoticed.

Remarks on Granular Citrate of Magnesia.—H. C. Archibald.—After referring to the so-called citrate of magnesia of the English trade, which the author states to be made up of tartaric acid, bicarbonate of soda, sugar, and a trace of magnesia, the author states that, to obtain a preparation that could be properly called granular citrate of magnesia, by the direct union of citric acid and magnesia, and having, at the same time, effervescing properties, was found to be impracticable. After a series of experiments to ascertain whether a granular salt could be made which would contain citrate of magnesia, and be at the same time effervescent and perfectly soluble, the following formula was adopted, which, if strictly adhered to, will afford a beautiful salt, possessing decided laxative properties and very acceptable to the palate:—Take of powdered citric acid, 4 lbs.; calcined magnesia, 1½ lbs.; bicarbonate of soda, 3 lbs.; tartaric acid, 3 lbs.; powdered white loaf sugar, 6 lbs.; essential oil of lemons, ½ fluid oz.; alcohol (very strong), q.s. To the powdered citric acid add the sugar, and mix thoroughly; then add the soda, magnesia, and tartaric acid. Pass the whole through a No. 40 sieve three times, to insure thorough mixture; moisten the powder with strong alcohol and pass through a No. 8 sieve and place on a wooden tray to dry, at a temperature of 120°F . Add the oil of lemons when dry, and bottle instantly in well dried and clean bottles. This preparation can be kept indefinitely without injury, is freely soluble in water without residue, has a pleasant taste, and is in very great request in the United States; undoubtedly, this preparation is far to be preferred above what goes by the name of effervescing citrate of magnesia in this country.

On a Brown Hair-Dye.—G. McDonald.—Under this title the author, in reality, makes known a fact which is worthy of notice; he says, the well-known fact that a soluble compound of lead and sulphur could not be obtained by the decomposition of a soluble lead salt by a soluble sulphuret, or, in other words, the insolubility of the sulphuret of lead was regarded as an indubitable proof of the folly of undertaking to search for a compound containing sulphuret of lead in a soluble state, and yet so as to be innocuous to the system. There is a class of salts known as hyposulphites, many of which are freely soluble in water, and which are readily converted by absorption of oxygen into sulphate of the base and free sulphur; it is in the use of these salts that the key to the enigma lies. Chemical text-books state that hyposulphite of lead is insoluble in water, which is quite correct; but, like many other precipitates insoluble in water, it is readily dissolved by an excess of the precipitant; thus, if we add to a solution of three parts of acetate of lead two parts of hyposulphite of soda, we shall have a curdy white precipitate of hyposulphite of lead, insoluble in water; but if we add to this ten parts more of hyposulphite of soda the precipitate will be re-dissolved, and a perfectly clear solution will be the result; this solution, when applied to the hair, is decomposed by absorption of oxygen; one of the results thereof is the formation of the dark brown sulphuret of lead, it is to the formation of this compound in the hair that all lead and sulphur dyes owe their efficacy.

Cosmos, May 21, 1870.

Reorganisation of the Ministry of Public Instruction.—By a decree, dated May 15th, M. Mège, Bâtonnier de l'Ordre des Avocats at Clermont Ferrand, has been appointed Minister of Public Instruction. This gentleman was born at Riom, September 15th, 1817; by a decree of the same date, there has been established a Ministry of Literature, Sciences, and Fine Arts, and a series of institutions, hitherto under the control of the Minister of Public Instruction, and among these the Imperial Institute, several libraries, and schools, have been placed under the newly established ministry.

Discovery of Fossil Bones near Durfort (Gard).—Cazalis de Foudouce.—The author, while on his way to Boumadas Morts, had his attention attracted by what appeared at some distance to be an elephant's tooth laying on a heap of stones, along the road from Alain to Vigan; on approaching the object he found it to be what he believed, and on making inquiry with the Cantonier (men stationed along the road during a portion of the day, to see to its being kept in proper repair; they are under the orders of the Ingénieurs des Ponts et Chasseurs) the stones (intended for the repair of the road) were traced to their origin; upon search being made near that spot, a tolerably complete skeleton of the *Elephas primigenius* was found in a locality where,

judging by its well-known geological features, this was hardly to be expected; the author relates at great length all the particulars, including the size of the parts of the animal recovered.

Chemical Treatment of Flax.—M. Magne.—The author treats this fibre alternately with weak caustic alkalis and alkaline hypochlorites, at temperatures ranging from 20° to 50°; the last trace of alkali is washed out with weak hydrochloric acid; the fibres thus prepared are stated to be bleached better than by any other process.

Testing Glue for its Good Quality.—Dr. Chabrier.—The author states that the best means of ascertaining the goodness of glue consists in estimating the quantity of pure gelatine it contains, and for this purpose he suggests the use of a solution of permanganate of mercury in water acidulated with nitric acid; the operation is carried out volumetrically, the solution of mercury salt being titrated with a solution of pure gelatine in known quantity dissolved in water.

May 28, 1870.

New Electro-Magnetic Apparatus.—Dr. Demazet.—The author describes, at length, an apparatus constructed by him, which appears to be an improvement of Siemens's; while making from 250 to 280 revolutions a minute, the lifting power of the magnet is 70 kilos., and under similar conditions a platinum wire, 0.8 m.m. thick and 20 centim. long, was rendered red-hot, and iron wire of the same thickness fused; the machine produces, per second of time, half a c.c. of gas by the decomposition of water.

Acclimatisation of the Eucalyptus Globulus.—Dr. Cloëz.—The tree alluded to, a native of Tasmania, is highly esteemed, both on account of the durability of its wood, which is very hard and superior to teak wood, and because its leaves contain a peculiar camphor-like essence, which dissolves caoutchouc more readily than sulphide of carbon does, and is also a solvent for copal; the tree is reputed to have febrifuge properties, because it is said that fever is never known where it is abundantly found. The neighbourhood of Paris is too cold, and the soil not suitable for its growth there; but in the southern parts of France, as well as in Spain (where the tree thrives well) this beautiful plant will be very useful as a forest tree; it reaches in its native clime enormous height and size.

Revue Hebdomadaire de Chimie, May 12, 1870.

Echardonnage of Wool by Chemical Means.—Dr. Schaller.—By *échardonnage* is understood an operation intended to destroy in wool the particles of straw and vegetable fibre accidentally adhering to it or left in it after having been treated with the teazle, still used sometimes in preference to the carding machine. The author impregnates the wool with a mixture of common salt and dilute sulphuric acid; the excess of this liquid is squeezed out between properly arranged cylinders, and the textile fibre is next exposed to a heat of 130°, which, aided by the hydrochloric acid evolved from the mixture above named, causes the carbonisation of the cellulose, leaving the wool untouched; this latter is next washed in a slightly alkaline liquid, and is then fit for the mechanical operations required before spinning the wool.

Manufacture of Red Lead from Nitrite of Lead.—M. Pichon.—After referring to the fact that the red lead (minium) of commerce almost always contains some metallic lead and some oxide of lead (massicot), incompletely oxidised, the author proposes to take nitrate of lead and granulated metallic lead in the proportions of one equiv. of nitrate to four of metal; these materials are placed in a cast-iron cauldron, lined inside with lead; water having been added, the mixture is heated to 60° or 80°; after two hours time a yellow sandy mass is found to have settled at the bottom of the vessel; the liquid should then be decanted into a leaden vessel, wherein the nitrite of lead soon crystallises; after the crystals have been drained they are decomposed by means of heat, by being placed for that purpose into retorts similar to those in use for the manufacture of nitric acid; the acid vapours given off are condensed by suitable means, and the oxide of lead, which is deep black coloured and perfectly homogenous, thus obtained is employed for the manufacture of red lead instead of massicot; the red lead thus produced is, according to the author, perfectly homogenous, free from lead, and its composition is $3\text{PbO}_4 + \text{PbO}_2$; there is a difference of opinion as regards the formula to be assigned to minium— $\text{PbO}_2 + 2\text{PbO}$ (Dumas); Pb_2O_3 , PbO (Winkelblech); $\text{Pb}_2\text{O}_3 + \text{PbO}$ (Longchamp); Pb_2O_3 (Mulder).

May 19, 1870.

Comparison between the Steam Generating Power of Coal when Burned, and of the Combustion of the Heavy Oils.—H. Sainte-Claire Deville.—This paper is a good abstract of the several papers which have appeared on this subject in the *Comptes Rendus*.

New Method of Copper Extraction, and its Separation from other Metals.—J. Elkington.—The principle applied by the author consists in applying electricity for dissolving the copper contained in the crude metal obtained by the usual smelting methods, and for depositing that metal galvanically upon plates of copper, causing the other foreign metals to fall to the bottom of the vessels in which the operations take place; copper, containing very small quantities of silver, may be advantageously treated thus for the recovery of the last-named metal.

So-called Annular Furnace or Kiln for the Continuous Operations of Burning Bricks, Lime, Porcelain, Cement, &c.—F. Hofmann.—Illustrated with woodcuts.

On the Salts of the Cerium Metals.—M. Zschiesche.—The author has studied some of the salts of the metals jointly found in the mineral cerite. Chloride of lanthanum, $\text{LaCl}_3 + 5\text{H}_2\text{O}$, forms large colourless crystals, which are not deliquescent; oxalic acid precipitates from acid solutions of didymium the oxalate of that metal in insoluble state similar to chloride of lead; on being heated to a redness it first yields a carbonate, and at a very high temperature a peroxide; the sulphate of didymium is $\text{DyOSO}_4 + 3\text{H}_2\text{O}$. Among the cerium salts the author studied the salt yielded by the oxide which results from the ignition of the oxalate of cerium; this oxide, when dissolved in sulphuric acid, yields a red-coloured salt— $5\text{CeOSO}_4 + \text{Ce}_2\text{O}_3 + 27\text{H}_2\text{O}$; and a yellow-coloured mixture of the last and some sulphate of protoxide.

Oxyhydrogen Blowpipe, called Universal.—M. Delaporte.—The chief point of difference of arrangement in this apparatus consists in having several jets for the hydrogen, and only one for the oxygen; this latter gas, the heavier, is made to fall as it were and convey the other. The effect is the production of a lance-shaped flame of great power; proper precautions are provided to prevent explosions.

Analysis of the Water of the Grosnard Spring intended to Supply the Town of St. Quentin.—J. Vivien.—Ten litres of this water contain, in grms.: Carbonate of soda, 0.0510; carbonate of lime, 2.3480; carbonate of magnesia, 0.1530; nitrate of lime, 0.4539; nitrate of magnesia, 0.0559; sulphate of lime, none; chloride of potassium, 0.2196; chloride of sodium, 0.1233; silicate of soda, 0.0371; free silica, 0.0170; organic matter, 0.0210; total, 3.3898.

NOTES AND QUERIES.

Phosphate of Ammonia.—Will any of your readers kindly furnish me with a process for the manufacture of phosphate of ammonia from bone-ash.—J. W. M.

Oxygenated Water.—Will any of the readers of the *CHEMICAL NEWS* oblige J. C. with the method and utensils adopted in the manufacture of oxygenated water, or say where he may gain such information?

Chrome Colour.—"Colourman" offers his best thanks for the answers given to his query. As *Dingler's Polytechnisches Journal* is not within his reach, may he trespass once more by asking if a formula is given for producing a good vermilion-red chrome colour?

Erecting Prism.—Referring to Prof. Morton's very ingenious plan of erecting the image given by a magic lantern, I beg to inform you that I have made the prism (Fig. 2, p. 246 of the *CHEMICAL NEWS*) some two or three years since, for Prof. Herschel, of the Andersonian College, Glasgow; and I have one of these prisms by me at present.—JOHN BROWNING.

Volumetric Estimation of Chlorine.—In the *CHEMICAL NEWS* (vol. xxi., p. 217), I notice the estimation of chlorine by means of nitrate of silver and chromate of potassium solution. The process is by no means new; it can be found at p. 183 of Sutton's "Volumetric Analysis," 1863. I used the method in various instances as far back as 1864, with much success.—T. B.

Tungsten Blue.—In the *CHEMICAL NEWS* (vol. xxi., p. 130) appears an extract from *Les Mondes* relating to tungsten blue. Will any one of your readers be kind enough to inform me whether he has succeeded in making the blue according to the process there given, and, if so, state his opinion of its value? Says the extract, it "is sold at the same price as the very best quality of Prussian blue." May I ask where a sample can be purchased?—T. W. S.

MEETINGS FOR THE WEEK.

- MONDAY, June 6th.—London Institution, 4.
Royal Institution, 2. General Monthly Meeting.
- TUESDAY, 7th.—Ethnological, 8.
Royal Institution, 3. Prof. Seeley, "On Present English History."
- WEDNESDAY, 8th.—Microscopical, 8.
Geological, 8.
- THURSDAY, 9th.—Royal Institution, 3. Prof. Tyndall, "On Electricity."
Zoological, 8.30.
- FRIDAY, 10th.—Royal Institution, 8. Prof. Odling, "Ammonia Compounds of Platinum."
Astronomical, 8.
Quekett Microscopical Club, 8.
- SATURDAY, 11th.—Royal Institution, 3. Prof. Grant, "Astronomy of Comets."
Quekett Microscopical Club. Excursion to Elstree. To meet at St. Pancras Station, at 1.30 p.m.

TO CORRESPONDENTS.

F.C.S.—We think it may.
T. Summers, jun., 1. The full account will be found in the *Bulletin de la Société d'Enseignement* for 1869, 2e série, t. xvi., p. 277. Apply to Asher and Co., Bedford Street, Covent Garden. 2. We know of no work devoted entirely to the subject; it is treated of in the *Dictionnaires of Chemistry*.

THE CHEMICAL NEWS.

VOL. XXI. No. 550.

NOTE ON THE HOMOLOGUES OF CUPRIC ACETO-ARSENITE (SCHWEINFURT GREEN).

By P. S. ABRAHAM, B.Sc.,
Exhibitor at the Royal College of Science, Dublin.

I HAVE recently found that, if cupric formate, butyrate, or valerianate be substituted for cupric acetate in the process for the manufacture of Schweinfurt green, compounds are obtained similar in colour to the well-known green, but containing formic, butyric, or valerianic acid in place of the acetic.

For the preparation of cupric formo-arsenite, 4 parts of cupric formate were dissolved in as little water as possible, and added to 4 parts of arsenious acid dissolved in about 50 parts of water by the aid of a little caustic soda; both solutions being at the boiling-point. The yellowish precipitate which appeared soon became of a very bright green, with a slightly more yellowish tinge than the acetic compound.

The butyric and valerianic greens were made in a similar manner, but with different proportions of cupric salt and arsenious acid,

NEW METHOD OF HEATING STONEWARE VESSELS, AND OF OBTAINING REGULATED HIGH TEMPERA- TURES.

IN conducting chemical and pharmaceutical operations for manufacturing purposes, it is generally necessary to effect evaporation and distillation in stoneware vessels; but great difficulty has been hitherto experienced in obtaining a sufficiently high temperature without cracking or breaking the pan employed. The use of a naked fire inevitably causes a fracture; and a sand-bath offers too great an obstruction to the passage of the heat. With a steam-jacket, it is impossible even to raise water to the boiling-point, unless, indeed, such a pressure of steam be applied as to cause a very dangerous strain on the flanges of the vessel.

A new method of applying heat, however, has been patented by Mr. J. A. Coffey, the pharmaceutical engineer, and is now introduced by Messrs. Doulton and Watts, for working stoneware pans and stills, by which any temperature ranging from 100° to 700° F. can be safely and easily obtained.

Mr. Coffey's principle is to cause heavy paraffin-oil to circulate, first through a coil of pipes in a furnace, and then through the jackets of the pans. The oil is carefully selected for the purpose, from the heaviest of the petroleum or paraffin products. It moves by its own convection. Heated in a close coil of pipe by a coke fire, it rises into an air-tight tank, from which it passes, through pipes, to the jackets of the different vessels to be heated, returning, after it has done its work, to the lowest part of the furnace-coil; a continuous circulation is thus maintained, similar to that which occurs in a hot-water apparatus for warming buildings. After leaving the tank, the oil passes

through a pyrometer, by which its temperature is indicated, and, by means of dampers, &c., to the fire this can be regulated to any required point. The heating medium is turned on or off the jackets by taps, in the same manner as steam; and, as the rate of flow can be checked or augmented at will, the temperature is perfectly under the control of the operator.

In the model which has been fitted up at Messrs. Doulton and Watts's to illustrate the principle of this method of working, the pyrometer generally indicates from 600° to 700° F., while a saturated solution of chloride of calcium is maintained at the boiling-point in a shallow stoneware pan. No smell of oil is perceptible in the room; and it is stated that the same oil may be used for years, without deterioration or causing any deposit in the pipes. As contrasted with steam-heat, the inventor claims for his process a saving of 30 per cent in fuel. It is obvious that the large amount of heat necessary to convert water at 212° F. into steam at 212° is hereby economised. The stoneware used in this process is manufactured expressly by Messrs. Doulton, to ensure its being quite impervious to the oil.

Other applications of this method of conveying heat are included in Mr. Coffey's patent; but its easy adaptation to heating stoneware will probably be of the most interest to chemists.

AMMONIUM AMALGAM AND HYDROGENIUM.

By Prof. C. A. SEELY.

At the meeting of the Chemical Section of the New York Lyceum of Natural History, May 9th, 1870, Prof. C. A. Seely read a paper "*On the Constitution of Ammoniacal Amalgam*," of which the following is an abstract:—

Ammonium amalgam was discovered by Berzelius in 1808, and immediately after by Pontin, Seebeck, and Trommsdorff. Its easy preparation, singular properties, and its relation to current theories, have made it familiar to all chemists; it led to the adoption of Ampere's ammonium theory, gave a great impetus to the theory of organic radicals, and revived the notions of the alchemists of the compound nature of metals. Early in this century, it led many to conclude that the base of nitrogen is a metal; and, at the present time, without doubt, has assisted in giving currency to the notion that hydrogen is a metal. Except for it, perhaps the crudity, hydrogenium, would not have been inflicted upon us. Of course it has occupied a conspicuous place in chemical literature; scores of papers, and at least two books, have been printed about it.

The name ammonium amalgam expresses the supposed constitution of the substance; the radical ammonium is represented as dissolved in, or united with, mercury. The ammonium is, moreover, conceded to be a solid or a liquid, and to have a truly metallic character; thus the latest and best authorities present the case. It is described, in nearly all treatises on chemistry, as if its constitution was as certainly ascertained as that of common salt. There have been, from the beginning, however, those who doubted the prevailing ideas, and some (see Daniell's "*Chemical Philosophy*," p. 520; and Dr. Wetherill on "*Ammonium Amalgam*," in *Silliman's Journal*, vol. xl., p. 160) boldly objected to them; but the reasons they alleged had not sufficient weight. Ammonium amalgam has always been a pet with chemists; it has always been ready for the service of one theory or another. The ammonium theory, the radical theory, the nitrogen and hydrogenium theories, have each, in their turn, been of too much importance to permit any of their props to be withdrawn.

The author considers the so-called ammonium amalgam

to be a mechanical or physical mixture of liquid mercury with the gases ammonia and hydrogen, and that its semi-solid consistence is due to the mixture having the nature of a froth. When sodium amalgam is brought into a solution of sal ammoniac (the ordinary method of preparing ammonium amalgam), the chlorine combines with the sodium, and the residue ($\text{NH}_3 + \text{H}$) of the sal ammoniac is set free all over the surface of the mercury; the particles of the mixed gases adhere to the mercury, and, by reason of the movement bringing to the surface fresh mercury, they become enfilmed and carried inward, until the mixture becomes a homogeneous froth. The principal considerations by which this view of the constitution of ammonium amalgam has been reached are as follows:—

1. The volume of ammonium amalgam is inexplicable in any other way. It is utterly inconsistent with the well-established laws of combinations by volume; there is no case of a liquid or solid chemical compound, or amalgam, which has any analogy to it.

2. Mercury has a mirror-like surface; while ammonium amalgam has comparatively a whiter and more dead surface: it approaches, in appearance, to matt silver. Such changes are characteristic of froths.

3. If ammonium amalgam be subjected to varying pressure, its volume changes, apparently, in accordance with Mariotte's law of gaseous volume. To illustrate this important fact, a glass tube, $\frac{1}{2}$ inch in diameter, 20 inches long, and fitted with a plunger, was employed. Mercury containing a little sodium was poured into the tube to $\frac{1}{2}$ inch in depth; and upon this was poured a strong solution of chloride of ammonium, occupying about 2 inches in length of the tube. The ammonium amalgam was completely formed in a few minutes, and occupies several inches of the tube. On adjusting and depressing the plunger, the volume of the amalgam progressively diminished till it closely approached the original volume of the mercury. Also, it was notable that the amalgam progressively gained fluidity and the mirror-surface, till, at the greatest pressure, it appeared like mercury. On withdrawing the pressure, the original volume and appearance of the compound were resumed; and, on reducing the pressure below that of the air, the amalgam still expanded, until it rose above the surface of the liquid in the tube. If the great pressure be maintained, more ammonium amalgam will be formed, the mass expanding progressively, apparently in accordance with the fact that the absorption or adhesion of gases to liquids is favoured by pressure. By means of the simple apparatus used, a pressure of ten atmospheres or a good vacuum are easily and at once obtainable, and the experiments with it are very striking.

The so-called ammonium amalgam is, therefore, not an amalgam at all. Ammonium is not proved to be a metal; and, if it be admitted that the monatomic radical really exists in ammonium amalgam, it is neither a solid nor a liquid, but a gas.

The considerations regarding ammonium amalgam are evidently equally applicable to Loew's hydrogenium amalgam; both are only metallic froths. The expansion of palladium observed by Graham, on its absorption of hydrogen, is probably analogous to the case in question. In both cases, the gases concerned are condensed, by reason of their attraction to the metal; and, if the molecules of palladium were made free to move, as those of mercury, it is probable that Graham's hydrogenium alloy would become a palladic froth, more remarkable than the corresponding mercuric froth. Many have erroneously supposed that hydrogen was conspicuous in its capability of being absorbed by metals, and thus have more readily been infused with the hydrogenium theory. Oxygen has an eminence over hydrogen in that property; and yet no one has a theory of oxygenium. Iron absorbs carbonic oxide; but no one is bold enough to suggest that carbonic oxide is a metal.—*American Gas-Light Journal*.

A PROCESS FOR QUICKLY AND ACCURATELY DETERMINING THE AMOUNT OF CHROMIUM AND IRON IN CHROME IRON ORES.*

By J. BLODGET BRITTON,
Ironmaster's Laboratory.

REDUCE the mineral to the finest state of division possible, in an agate mortar. Weigh off 0.5 grm. and add to it 4.0 grms. of a flux, previously prepared, composed of one part chlorate of potassa and three parts soda-lime; thoroughly mix the mass by triturating in a porcelain mortar, and then ignite in a covered platinum crucible at a bright-red heat for an hour and a half or more. The mass will not fuse, but when cold can be turned out of the crucible by a few gentle taps, leaving the interior of the vessel clean and bright. Triturate in the mortar again and turn the powder into a tall 4-oz. beaker and add about 18 c.c. of hot water, and boil for two or three minutes; when cold, add 15 c.c. of hydrochloric acid of common strength, and stir with a glass rod for a few minutes, till the solid matter, with the exception, probably, of a little silica in a flaky gelatinous state, becomes dissolved. Both the iron and chromium will then be in the highest state of oxidation— Fe_2O_3 and CrO_3 . Pour the fluid into a white porcelain dish of about 20 ozs. capacity, and dilute with washings of the beaker to about 3 ozs. Immediately after, also, pour cautiously into the dish 1.0 grm. of metallic iron of known purity, previously dissolved in dilute sulphuric acid and further diluted with cold water to about 5 ozs., to make up the volume in the dish to about 8 ozs. (I use for the purpose fresh borings from a piece of bar iron, containing less than 0.05 of foreign matter, dissolved in 18 c.c. of dilute sulphuric acid of 1 part acid and 3 $\frac{1}{2}$ parts water, in a tube 12 inches long and $\frac{1}{2}$ inch diameter, closed at the top with a gum stopper perforated for a $\frac{1}{4}$ inch tube, bent short round at right angles and extending horizontally about three or four inches, applying heat to expel atmospheric air and facilitate operations). When the iron is dissolved, and having tested the solution for sesquioxide, I nearly fill the tube with cold water and cautiously pour the contents into the dish and add about two tubes-full more of cold water to make up the solution to about 8 ozs., and then determine, volumetrically, with a standard solution of permanganate of potash, the amount of protoxide of iron remaining. The difference between the amount of iron found and of the iron weighed will be the amount oxidised to sesquioxide by the chromic acid. Every one part so oxidised will represent 0.320 of metallic chromium, or 0.4663 of sesquioxide, Cr_2O_3 , in which last condition the substance usually exists in the ore.

If the amount of iron only in the ore is to be determined, the process is still shorter. After the fluxed mineral has been ignited and reduced to powder, as already directed, dissolve it in a tube of the kind described, by adding, first, 10 c.c. of hot water and applying a gentle heat, and then 15 c.c. of hydrochloric acid, continuing the heat to incipient boiling till complete decomposition has been effected; cool by immersing the tube in a bath of cold water, add pieces of pure metallic zinc (sheet zinc cut in small strips I prefer) sufficient to bring the iron to the condition of protoxide and the chromium to sesquioxide, and apply heat till small bubbles of hydrogen cease, and the zinc has become quite dissolved; then nearly fill the tube with cold water, acidulated with 1.10th of sulphuric acid, and pour the contents into the porcelain dish, add cold water to make up the volume to about 8 ozs., and complete the operation with the standard permanganate solution.

The process, if conducted as directed, affords very accurate results; upon repeating the determinations there should be practically no variation. The whole time

* Communicated by Professor Morton.

consumed need not exceed three hours to determine both the chromium and the iron, if the two ignitions are proceeded with simultaneously.

It need scarcely be remarked that fine iron wire or ammonio-protosulphate of iron may, in most cases, be used with greater convenience than borings. I, however, in my own practice, prefer the latter, and for several years past have kept in the laboratory for use a large piece of iron of the kind mentioned, from which, by the aid of a small foot-lathe, I obtain in a moment or two clean unoxidised borings whenever they are needed, and thus have an unalterable standard always at hand.

For dissolving minerals and metals, I constantly use tubes of the kind described, though sometimes of a larger size, preferring them generally to all other vessels for many reasons:—avoidance of loss of substance, convenience of rinsing, expulsion of air while digesting and boiling, carrying out of the laboratory all of the evolved gases by means of the small bent tubes leading into a chamber connected with the main chimney, &c.

When determining iron volumetrically with the permanganate solution, I also always use the cold water acidulated with sulphuric acid, when hydrochloric acid has been the solvent, because with it the final relation is more distinct and the results more constant; besides, if previously prepared in quantity, and cold, it at once reduces the temperature of the hot fluid, and so saves time.—*Journal of the Franklin Institute.*

ON THE

ESTIMATION OF PEROXIDE OF MANGANESE IN MANGANESE ORES.*

By JOHN PATTINSON, F.C.S.

It has long been known that very varying results have been obtained by different analysts in operating upon the same samples of manganese ore, and, very naturally, these discrepancies have been a source of great annoyance to both sellers and purchasers of these ores. In their attempts to find the cause of these differences, Messrs. Teschemacher and Smith were led to the discovery that many manganese ores now in the market contain magnetic oxide of iron. It is said that this substance appropriates a portion of the peroxide of manganese in the ore when the sample is tested by what is known as the iron method of estimation, but not when tested by Fresenius and Will's oxalic acid method; in other words, that the iron process indicates only the *available* amount of peroxide of manganese in the ore, and the Fresenius and Will process the *absolute* amount; and hence, they say, the differences in the results found by the various analysts who use these two methods. This theory may, possibly, be correct in some cases, but it is certain that this is not the only reason why the Fresenius and Will process gives higher results than the iron process in testing certain ores, I have met with several samples of manganese ore containing considerable quantities of magnetic oxide of iron, but I have never yet met with one the magnetic oxide of which was not fully oxidised at the expense of the peroxide of manganese of the ore on being tested by Fresenius and Will's method. Before proceeding further it will be desirable to consider what takes place when the Fresenius and Will test is applied in the presence of protoxide of iron. If the protoxide of iron is in the soluble state it is entirely peroxidised by the oxygen of the peroxide of manganese, and the test indicates a relatively less amount of peroxide in the ore examined. This was proved by the following experiment:—30 grs. of a soft and easily decomposed manganese ore free from magnetic oxide and known

to contain by the Fresenius and Will test 63·36 per cent of peroxide, together with 70 grs. of neutral oxalate of potash, 20 grs. of proto-sulphate of iron containing 3·90 grs. of iron in the state of protoxide, and some water, were treated in the usual way according to the Fresenius and Will method. The percentage of peroxide indicated by the loss of carbonic acid was 53·13, showing that the protoxide of iron in the proto-sulphate had appropriated 10·23 per cent of peroxide. Theory requires 10·21 per cent of peroxide to effect the oxidation of all the iron. The effect is different when the protoxide of iron in the ore is in the insoluble state, as, for instance, when magnetic oxide is present. In this case the protoxide is only peroxidised as it becomes dissolved. It is possible that ores containing magnetic oxide may exist which have their peroxide in a condition in which it is so easily decomposed by oxalic acid that the whole may be decomposed before the magnetic oxide has been at all dissolved. In this case the test would indicate the *absolute* amount of peroxide in the ore. That such a condition may obtain is seen by the following experiment:—25 grs. of an ore similar to that used in the last experiment but containing 63·60 per cent of peroxide by both the iron and oxalic acid tests, together with 60 grs. of neutral oxalate of potash, 5 grs. of very finely-powdered magnetic oxide of iron known to contain 18·6 per cent of iron as protoxide, and some water, were placed in the Fresenius and Will apparatus. On testing in the usual way, the loss of carbonic acid indicated 63·50 per cent of peroxide, or within 0·1 of a per cent of what it was without the magnetic oxide. The magnetic oxide, however, was apparently but very slightly, if at all, affected. A further quantity of sulphuric acid was then added, and heat applied until the solution of the magnetic oxide was completed. The amount of iron existing in the solution was then determined by a standard solution of bichromate of potash. It indicated 1·08 grs. of iron in this condition. The amount in the five grains of magnetic oxide was 0·93 grs. The excess is accounted for by the fact that the oxalic acid in the solution somewhat interferes with the bichromate of potash test for iron.

I have said it is possible that ores of the character described above may exist—ores in which the Fresenius and Will test will indicate the absolute amount of peroxide they contain; but I have never met with such ores. Those I have seen containing magnetic oxide of iron (and some samples have contained a considerable amount) have had this substance so intimately diffused throughout the ore, and have had their peroxide in a condition so difficult to decompose, that the magnetic oxide has been quite dissolved before, or as soon as the complete decomposition of the peroxide has been effected. This was easily proved by testing the resulting solution of manganese and iron for protoxide of iron by means of a few drops of a solution of red prussiate of potash added to the dilute solution. It is obvious that, if after completed decomposition of the ore, the manganese has not peroxidised the whole of the protoxide of the magnetic ore, its presence would be detected by the above test. *In no case have I found any proto-salt of iron in the resulting solutions.* Therefore, in all the cases I have met with, some of the peroxide of the ore has been appropriated to completely peroxidise the magnetic ore, and the Fresenius and Will test, in these cases, does not indicate the absolute amount of peroxide contained in the ores.

In my opinion, the more likely explanation of the cause of the discrepancies between the various tests is to be found in the great difficulty with which these hard ores containing magnetic oxide of iron are decomposed in the Fresenius and Will apparatus. In order to effect their decomposition it is necessary to add a large quantity of sulphuric acid, and to apply extraneous heat for a considerable time. It is probable that, during this lengthened heating, steam is allowed to escape with the carbonic acid, and hence a higher amount of peroxide is indicated than is present in the ore.

* Read before the Newcastle-upon-Tyne Chemical Society, January 27, 1870.

But whichever theory is correct, both lead to the same conclusion that with such hard ores the Fresenius and Will test gives inaccurate results, and therefore should be abandoned. For soft and easily decomposed ores I believe its indications are very correct; but as several of the other class of ores are now in the market, it is necessary to have some process by which the available peroxide contained in all kinds can be correctly determined.

The iron process is one which is now in very general use, and has usually been found to give very good results.

In the paper "On the Estimation of Peroxide of Manganese in Manganese Ores," by Messrs E. Sherer and G. Rumpf, read before the members of this society at their meeting in November last, these gentlemen show that they had obtained inaccurate and irregular results in their experiments with this method as followed by them. They had used pianoforte wire dissolved in a flask with hydrochloric acid, adding the manganese ore in a glass tube, and taking the precaution of keeping an atmosphere of carbonic acid in the flask during the whole process to prevent oxidation by atmospheric air. They attributed the irregularity of the results they had obtained, and correctly I think, to the circumstance that portions of the manganese ore are occasionally floated to the surface of the solution where they evolve chlorine, which escapes without coming into contact with the proto-salt of iron in solution. That this process can be made to yield correct results, by taking precautions to prevent this escape of chlorine, the authors themselves have shown. Fresenius also states in his handbook that the results he obtained by this process agreed exactly with those obtained by that of Fresenius and Will. Messrs. Sherer and Rumpf come to the conclusion that, of the methods they experimented with, Bunsen's gave the most correct results, and that this method was much simpler and shorter of execution than the iron method when the necessary precautions to insure accuracy were employed in the latter process.

In the discussion which followed the reading of this paper I stated that, being aware of the source of error the authors had pointed out, I had, for some time past, used in my laboratory a modification of the iron process by means of which the source of error was avoided, and perfectly accurate and concordant results obtained; and that the modified process was, in my opinion, more easy of execution (requiring less skill and care at the hands of the operator) than the Bunsen method of estimation. In fulfilment of a promise I then made I have now to describe the manner in which I proceed when testing manganese ores by the iron method.

30 grs. of clean iron wire are placed in a 20 oz. flask, along with 3 ozs. of dilute sulphuric acid, made by adding 3 parts of water to 1 of oil of vitriol. A cork, through which passes a tube bent twice at right angles, is inserted in the neck of the flask, and the flask is heated over a gas flame until the iron is dissolved. The bent tube is placed so as to dip into a small flask or beaker containing a little water. When the iron is quite dissolved, 30 grs. of the finely-pounded and dried sample of manganese ore to be tested are put into the flask, the cork replaced, and the contents again made to boil gently over a gas flame until it is seen that the whole of the black part of the manganese is dissolved. The water in the small flask or beaker is then allowed to recede through the bent tube into the larger flask, more distilled water is added to rinse out the small flask or beaker and bent tube, the cork well ringed, and the contents of the flask made up to about 8 or 10 ozs. with distilled water. The amount of iron remaining unoxidised in the solution is then ascertained by means of a standard solution of bichromate of potash. The amount the bichromate indicates, deducted from the total amount of iron used, gives the amount of iron which has been peroxidised by the manganese ore, and from which can be calculated the percentage of peroxide of manganese contained in the ore. Thus, supposing it were found that 4 grs. of iron remained unoxidised, then

30-4=26 grs. of iron which have been oxidised by the 30 grs. of ore. Then, as

Iron.	Peroxide of Manganese.	Iron.	Peroxide of Manganese.
56	: 44	: 26	: 20.43

the amount of peroxide in the 30 grs. of ore. The percentage is, therefore, 68.10.

It will be seen, from the above description, that the only differences between this method and that usually described in hand-books are the use of sulphuric acid instead of hydrochloric acid, and the dispensing with the use of a stream of carbonic acid. These alterations, however, enable us to get rid of the source of error indicated by Messrs. Sherer and Rumpf, and also of the somewhat complicated and troublesome apparatus required to supply a stream of carbonic acid.

In order to determine the accuracy of this method, some samples of soft and easily-decomposed manganese ore known to be free from magnetic oxide, were tested by Fresenius and Will's method, and compared with the results obtained by the iron method. The results obtained were as follows:—

By Fresenius and Will's Process.	By Iron Process.
63.36 per cent	63.43 per cent
82.34 "	82.34 "
74.00 "	73.98 "
63.32 "	63.25 "

That by the iron method results can be obtained which agree very closely with each other will be seen by the following statement:—Of 85 samples tested in duplicate by this method 22 were exactly the same in the two results, 54 were within 0.1 of a per cent of each other, 8 were within 0.2 of a per cent, and 1 differed 0.2 of a per cent in the two tests.

The use of sulphuric acid instead of hydrochloric acid not only gets rid of the before-mentioned source of error, but it is also the reason why the carbonic acid atmosphere can be dispensed with. I have ascertained that the solution of iron in sulphuric acid does not oxidise appreciably by exposure to air within any reasonable time; certainly not within the time required to make the test. A sample of manganese ore tested after allowing the iron solution to cool in an atmosphere of carbonic acid, and taking precautions to prevent the admission of air, indicated 63.98 per cent of peroxide by two separate tests. Another portion of the same ore was tested after another portion of iron had been simply allowed to cool in air and to stand one hour before adding the manganese ore. It indicated exactly the same as the sample cooled in carbonic acid, viz.:—63.98 per cent. Another sample, after the iron solution had been allowed to stand two hours exposed to the air, still indicated 63.98 per cent of peroxide. After 19 hours' exposure of another portion the ore indicated 63.96 per cent. There was, therefore, no practical difference in the amount of iron existing as protoxide in any of these solutions. In another experiment a sample of manganese ore, which had indicated 64.45 per cent of peroxide on cooling the iron in carbonic acid, indicated 64.50 per cent after the iron solution had been exposed to the air for six hours, and 64.69 per cent after the iron solution had been exposed to the air during 48 hours. In the last case the iron had become oxidised to a slight extent, but in the case of the iron exposed for six hours little or no oxidation had occurred.

The same results have been repeatedly obtained in other experiments.

The solution of iron in hydrochloric acid oxidises much more rapidly. 7 grs. of iron wire dissolved in hydrochloric acid, and allowed to stand 18 hours exposed to the air in a flask with a cork through which passed an open tube, indicated 6.2 grs. of iron existing as a proto-salt; whilst 7 grs. dissolved in sulphuric acid, and exposed for the same length of time, under the same circumstances, indicated 6.995 of iron existing as a proto-salt.

The kind of iron wire I have found to answer best for these analyses is the kind used by wire-workers, and known as "annealed iron wire." Only the purest qualities of iron are used for wire of this description. I have carefully examined it by comparing it with pure oxalic acid and pure bichromate of potash, as well as by heating it in an atmosphere of chlorine, and find that it is within about 0.1 of a per cent of being absolutely pure. For all practical purposes of testing it may, therefore, be considered pure. There is no difficulty in obtaining it in large quantity and of uniform quality. I have tested wire of this kind of such thickness that 22 wires laid close together cover an inch, and I find it of equally pure quality as that which requires about 85 wires to the inch. I prefer the latter because it is more easily cut and dissolved, and it is more likely to be pure. Pianoforte wire, which is made of steel, will not do, excepting a correction is made for the amount of carbon it contains. I have found wire of this kind which contains only 98.50 per cent of pure iron. The odour of the hydrogen evolved during solution is a good indication of the purity of the iron. With steel wires the odour of carburetted hydrogen is very strong, but with the annealed iron wire it is very slight. In all cases it will be desirable to ascertain the purity of every new batch of iron wire obtained previous to its being used for testing manganese ores. Having once obtained wire of known purity, all future batches may be most easily and correctly tested by comparing the amount of peroxide of manganese, and, consequently of iron, indicated by a certain ore when tested by the new wire with the amount indicated when tested by the wire of known purity. The wire is easily cleaned from all adhering oxide and dirt by passing it a few times through fine emery paper and afterwards through a cloth. It is dissolved by the sulphuric acid in about fifteen minutes. I do not like to use crystals of protosulphate of iron, nor of the double sulphate of iron and ammonia, on account of the uncertainty of their composition. I have never yet met with either of these in so pure a condition as the iron wire. Besides there is no advantage in their use. It is quite as easy to weigh the iron wire as to weigh crystals of protosulphate of iron. I have tried a standard solution of protosulphate of iron, but find it does not keep sufficiently well to make it worth while to use this.

The use of the small flask or beaker in connection with the bent tube is to prevent all loss of iron by its being carried over with the hydrogen and steam. I have, occasionally, found a slight trace of the iron thus carried over through the tube, but this is, of course, all arrested by the water in the small beaker or flask, and is again returned into the larger flask when the tube is rinsed out.

The length of time required to decompose the manganese ore depends upon the hardness of the sample under examination, and this mode of testing thus affords a good indication of the nature of the ore in this respect. Soft ores will be decomposed in a minute or two, whilst very hard ores require fifteen minutes or more. The decomposition can be hastened by adding more oil of vitriol, but this must be done after the iron is dissolved, as the latter does not readily dissolve in stronger acid than that I have mentioned.

The standard bichromate of potash solution I use is made so that 1000 fluid grains will peroxidise 10 grains of iron. It is applied to the diluted solution in the usual way.

If there is reason to suppose that the ore to be tested contains more than about 78 per cent of peroxide, it will then, of course, be necessary to use less than 30 grs. of ore or more than 30 grs. of iron; as these quantities are only intended for ores of a lower percentage than about 78.

In order to facilitate and check the calculation of the percentage results, I have a table drawn up which shows the various percentages in the ores corresponding to every five grains of the bichromate solution, based upon the assumption that 30 grs. of iron and 30 grs. of ore are used.

In conclusion, I have to say that, with respect to the Bunsen method of estimation, it has given me unsatisfactory and variable results so far as I have tried it. I have, however, not yet completed my investigations into this method.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 2nd, 1870.

Professor WILLIAMSON, F.R.S., President, in the Chair.

MR. W. B. TUSTIN was elected a Fellow.

Professor ODLING, F.R.S., delivered a lecture "On the Platinum-Ammonia Compounds." The lecturer made by way of preface the following remarks:—One atom of platinum combines with four atoms of chlorine to form platinum chloride, PtCl_4 . In another compound of platinum and chlorine the latter is just one-half of that in platinum chloride, and this platinumous chloride may be represented either by the formula Pt_2Cl_4 or by PtCl_2 . Dr. Odling assumes the latter one to be correct, observing, on this occasion, that in chemical theory any assumption may be made, provided it is kept always in mind that it is only an assumption. All platinum-ammonia compounds are produced in the first instance from PtCl_2 ,—none of them directly from PtCl_4 . Just like platinumous chloride is, through direct combination with chlorine, transformed into platinum chloride, so the platinumous ammonia compounds, by direct union with chlorine, form platinum ammonia compounds. This view will at once introduce simplicity in the study of these compounds. The lecturer next proceeded to consider the right manner of expressing the constitution of sal-ammoniac. The decided analogy of this salt with potassium boro-fluoride, $\text{BF}_3 \cdot \text{KF}$; potassium silico-fluoride, $\text{SiF}_4 \cdot \text{K}_2\text{F}_2$, and potassium platinochloride, $\text{PtCl}_4 \cdot \text{K}_2\text{Cl}_2$, as well as many other evidences, do not permit to represent sal-ammoniac as NH_4Cl , that is

as if by union of hydrochloric acid with ammonia the chlorine would leave its hydrogen in order to combine with nitrogen,—a supposition wholly unwarranted from all the facts known with regard to the affinities of these two elements for one another; the formula of sal-ammoniac must be $\text{NH}_3 \cdot \text{HCl}$. From this salt two sets of metallic compounds are derived; in the one set the metal can be detected by the ordinary tests, in the other this cannot be done; the former may be typified by the formula $\text{NH}_3 \cdot m\text{Cl}$,* the latter by $\text{NH}_2 \cdot m\text{HCl}$. An example of the first set is the copper compound, $\text{NH}_3 \cdot \text{CuCl}$, from whose solutions the metal is precipitated as sulphide by hydric sulphide, and, with liberation of ammonia, as oxide by an alkali hydrate. An illustration of the second kind of metallic derivatives of sal-ammoniac is the platinum compound $\text{NH}_2 \cdot \text{PtHCl}$; in the solutions of this combination the platinum cannot be recognised by hydric sulphide, or alkali hydrate.

Dr. Odling then continued by drawing his comparison between the manifestations of the atomicity of nitrogen and those of the atomicity of carbon, showing that, like the tetradicity of carbon, is manifested not only in marsh gas and in methyl-chloride, but equally in ethyl-chloride, propyl-chloride, &c., so the pentadicity of nitrogen is not only manifested in sal-ammoniac, but equally in diammonio-argentic chloride, triammonio-cupric chloride, &c. The lecturer,

* The small letter here, and in the following formulae, indicates that quantity of a metal which fills the place of one atom of hydrogen.

closed his prefatory observations by declaring his belief in the necessity of studying mineral chemistry in the light of organic chemistry, in order better to understand the reactions and processes of the former. He then gave a short history of the platinum-ammonia compounds, beginning with the so-called green salt discovered by Magnus in 1828, mentioning the salts prepared and described by Gros, Reiset, Peyronne, and others, and finally stating Laurent and Gerhardt's arrangements to classify these compounds. This classification is by no means satisfactory, and having pointed out some of its shortcomings, Dr. Odling concluded his lecture by promising to bring forward at some future meeting his own views on this subject.

ROYAL INSTITUTION OF GREAT BRITAIN.

Notes of a Course of Seven Lectures on Electrical Phenomena and Theories. By Professor TYNDALL, LL.D., F.R.S. (Lecture IV.)

Historic Jottings, concerning Conduction and the Leyden-jar.

119. In 1727, Stephen Grey, pensioner of the Charter House, discovered electric conduction. Connecting an end of a wire 700 feet long with a glass tube and supporting the wire on loops of silk, he found that on rubbing the tube the distant end of his wire became electrified and attracted light bodies. He also found that a wire loop did not answer as a support, as the electricity escaped through it; hence arose the division of bodies into conductors and insulators. Grey's observations were written down by the Secretary of the Royal Society the day before his death.

120. In October, 1745, Von Kleist, a bishop of Cammin, in Pomerania, charged with electricity a flask containing sometimes mercury, sometimes alcohol. Through a cork in the neck of the flask passed an iron nail, which was brought into contact with the conductor of an electrical machine. On touching the nail Von Kleist experienced a violent shock.

121. In January, 1746, Cunæus of Leyden received also a shock, and his experiment was repeated by Allamand and Musschenbroek. A wire passed from the conductor of the machine into a flask filled with water. Musschenbroek held the flask in the right hand, the machine was turned, and then with the left hand he drew a spark from the conductor. The shock received was, according to Musschenbroek, so terrible, that he declared he would not receive a second for the crown of France. Musschenbroek observed that it was only the person who held the flask in his hand that felt the shock. Kleist failed to recognise this condition.

122. In Germany the jar is sometimes called Kleist's jar, but more commonly, because of the failure just referred to, the Leyden-jar. The theory of it, and other similar apparatus, was given by Franklin in September, 1747. (See Notes 81, 88, 89, 90.)

123. In 1747, Dr. Watson, Bishop of Llandaff, sent the discharge from a Leyden-jar through 2800 feet of wire, and through the same distance of earth. Subsequently, in the same year, he sent the discharge through 10,600 feet of wire, supported by insulators of baked wood. The experiment was made on Shooter's Hill.

124. In 1748 similar experiments were made by Franklin across the Schuylkill, and by De Luc across the Lake of Geneva.

Historic Jottings, concerning the Electric Telegraph.

125. The first proposal of an electric telegraph was made by an anonymous contributor to the *Scot's Magazine* for 1753. Various attempts to apply frictional electricity for this purpose were subsequently made. They culminated in the exceedingly ingenious arrange-

ment of Mr., now Sir Francis, Ronalds, published in 1823.

126. The voltaic pile was described by Volta in a letter to Sir Joseph Banks, written from Como in 1800.

127. Immediately afterwards Nicholson and Carlisle discovered the decomposition of water by the voltaic current.

128. In 1808 Sümmering proposed a system of telegraphy based on the discovery of Nicholson and Carlisle. A similar system was proposed about the same time by Prof. Cox, of Pennsylvania.

129. In 1820 CErsted discovered the deflection of a magnetic needle by an electric current.*

130. The idea of employing the deflection of the needle for telegraphic purposes occurred to the celebrated French mathematician, La Place; the problem was partly worked out by Ampère, and still further advanced by Ritchie, Professor of Natural Philosophy in the Royal Institution.

131. In 1832 Baron Schilling constructed models of a telegraphic apparatus, which were exhibited before the Emperors Alexander and Nicholas.

132. In 1833 Gauss and Weber established an electric telegraph between the Physical Cabinet and the Astronomical and Magnetic Observatories of Göttingen, embracing a distance of nearly 10,000 feet. Faraday's electricity instead of Volta's was employed by Gauss and Weber.

133. Steinheil was requested by Gauss to pursue the subject. To the telegraph he made many highly important contributions and suggestions. In 1837 he had established a system of wires about 40,000 feet in length, connecting various points in the city of Munich and its neighbourhood. The most considerable discovery of Steinheil, and indeed one of the most practically important hitherto made in connection with telegraphy, is that the "return wire" between two stations might be dispensed with, and the earth employed in its stead.

134. In 1834 Wheatstone, by means of a rotating mirror, made his celebrated experiments on the velocity of electricity. In the following year he exhibited one of Baron Schilling's telegraphs in his lectures at King's College.

135. In 1836 Mr. William Fothergill Cooke saw in the lectures of Professor Muncke, at Heidelberg, the performance of a similar instrument. Struck by its obvious practical importance, he devised a system of telegraphy, and, in partnership with Wheatstone, dating from June, 1837, succeeded in introducing the telegraphic system into England.

136. From 1832 to 1836 Morse sought to apply chemical decomposition by the electric current to telegraphic purposes; he abandoned this for his electro-magnetic system devised in 1836. This method consists in stamping, by means of the attraction of an electro-magnet, dots and lines upon a slip of paper caused to move by proper mechanism over the circumference of a wheel.

137. In 1850 the first submarine cable was laid by Mr. Brett between Dover and Calais. It survived only a day. In 1851 another cable was laid down, which proved successful.

138. On the 5th of August, 1858, the submergence of the first Atlantic cable was completed, and messages were sent between England and America. The cable ceased to act on the 4th of September, or about a month after its submersion.

* In his exceedingly useful little book on the Telegraph, published in Weale's "Rudimentary Series," Mr. Robert Sabine quotes the following remarkable passage from a work on magnetism, published in Paris, by Professor Izarn, in 1804:—"D'après les observations de Romagnesi, physicien de Trente, l'aiguille déjà aimantée, et que l'on soumet ainsi au courant galvanique, éprouve une déviation; et d'après celles de J. Majon, savant chimiste de Gênes, les aiguilles non-aimantées acquièrent par ce moyen, une sorte de polarité magnétique." The work containing this passage was lent to Mr. Sabine by Mr. Latimer Clark.

139. In 1865 the second Atlantic cable was laid and lost. In 1866 a cable was successfully laid, and in the same year the cable of 1865 was recovered. Messages are now sent between England and America at the rate of fourteen words per minute.

Phenomena observed in Telegraph Cables.

140. Davy showed ("Elements of Chemical Philosophy," 1812, p. 154) that a Leyden-battery could be charged with voltaic electricity.*

141. Dr. Werner Siemens was the first to employ (in 1847) gutta-percha as a means of insulating subterranean telegraph wires. On the 18th of January, 1850, in a paper communicated to the Physical Society of Berlin, he stated that a subterranean wire covered with gutta-percha, and surrounded by the moisture of the earth, behaved like a colossal Leyden-jar. He also found that ordinary telegraph wires charged themselves, though in a much smaller degree than the subterranean wires.

142. In 1838 Faraday predicted the retardation of the electric discharge by its own inductive action. ("Experimental Researches," 1333. "Faraday as a Discoverer," New Edition, p. 89.)

143. In 1854 Faraday experimented with cables at the gutta-percha works of the Electric Telegraph Company. One hundred miles of gutta-percha covered wire were immersed in water, and a second hundred miles of a similar wire were placed in a dry tank. We will call the former the water wire, and the latter the air wire.

144. Connecting one pole of a battery with the earth, and connecting the other pole with one of the two insulated ends of the water wire, on breaking the connection and touching the wire a powerful shock was received;

* Davy thus describes the celebrated battery with which he made this experiment. The spirit to which the battery owed its birth has not diminished among the members of the Royal Institution:—"The most powerful combination that exists in which number of alternations is combined with extent of surface, is that constructed by the subscriptions of a few zealous cultivators and patrons of science, in the laboratory of the Royal Institution (in 1808). It consists of two hundred instruments, connected together in regular order, each composed of ten double plates, arranged in cells of porcelain, and containing in each plate thirty-two square inches; so that the whole number of double plates is 2000, and the whole surface 128,000 square inches. This battery, when the cells were filled with 60 parts of water mixed with 1 part of nitric acid, and one part of sulphuric acid, afforded a series of brilliant and impressive effects. When pieces of charcoal about an inch long and one-sixth of an inch in diameter were brought near each other (within the thirtieth or fortieth part of an inch), a bright spark was produced, and more than half the volume of the charcoal became ignited to whiteness, and, by withdrawing the points from each other, a constant discharge took place through the heated air, in a space equal at least to four inches, producing a most brilliant ascending arch of light, broad, and conical in form in the middle. When any substance was introduced into this arch, it instantly became ignited; platinum melted as readily in it as wax in the flame of a common candle; quartz, the sapphire, magnesia, lime, all entered into fusion; fragments of diamond, and points of charcoal and plumbago, rapidly disappeared, and seemed to evaporate in it, even when the connection was made in a receiver exhausted by the air-pump; but there was no evidence of their having previously undergone fusion.

"When the communication between the points positively and negatively electrified was made in air rarefied in the receiver of the air-pump, the distance at which the discharge took place increased as the exhaustion was made, and when the atmosphere in the vessel supported only one-fourth of an inch of mercury in the barometrical gauge, the sparks passed through a space of nearly half an inch; and by withdrawing the points from each other the discharge was made through six or seven inches, producing a most beautiful coruscation of purple light, the charcoal became intensely ignited, and some platinum wire attached to it, fused with brilliant scintillations, and fell in large globules upon the plate of the pump. All the phenomena of chemical decomposition were produced with intense rapidity by this combination. When the points of charcoal were brought near each other in non-conducting fluids, such as oils, ether, and oxymercatic compounds, brilliant sparks occurred, and elastic matter was rapidly generated; and such was the intensity of the electricity, that sparks were produced, even in good imperfect conductors, such as the nitric and sulphuric acids.

"When the two conductors from the ends of the combination were connected with a Leyden battery, one with the internal, the other with the external coating, the battery instantly became charged, and on removing the wires, and making the proper connections, either a shock or a spark could be perceived; and the least possible time of contact was sufficient to renew the charge to its full intensity."

the discharge from the wire was also competent to ignite a Statham fuze. When, after having been in contact with the battery, the wire was separated and connected with a galvanometer, the instrument was powerfully affected.

145. A rush of electricity into the wire was declared by the galvanometer when contact was made; a rush out of the wire was declared when the wire between the battery and the galvanometer was connected with the earth. None of these effects were observed with the 100 miles of air wire.

146. Faraday, like Werner Siemens, rightly explained the effect by likening the cable to an enormous Leyden-jar, the wire constituting the interior, the water the interior coating, with the gutta-percha insulator between them. In fact, the surface of the wire in these experiments amounted to 8300 square feet, while the surface of the outer coating of water was 33,000 square feet. To the charge and discharge of this apparatus the effects observed were due.

147. In a subterranean line of telegraph 1500 miles long were placed three galvanometers: one *a*, at the beginning of the wire; a second, *b*, in the middle; and a third, *c*, at the end, which was also connected with the earth.

148. Connecting the battery with the wire of the galvanometer *a*, that instrument was instantly affected; after a sensible time *b* was affected; and after a still longer time, *c*. It required, in fact, two seconds for the electric stream to reach the last instrument.

149. All the instruments being deflected, when the battery was suddenly cut off at *a*, that instrument instantly fell to zero, *b* fell subsequently, and *c* after a still longer interval.

150. By a brief touch of the battery-pole against *a*, that instrument was deflected, and could be allowed to fall back into its neutral condition before the electric power had reached *b*; *b* in its turn would be affected, and left neutral before the power had reached *c*.

151. In this case a wave of force was sent into the wire which gradually travelled along it, appearing in different parts of the wire at successive intervals of time.

152. It was even possible, by adjusted touches of the battery, to make several successive waves co-exist in the wire.

153. When, after making and breaking contact at *a*, that galvanometer was connected with the earth, part of the electricity sent into the wire returned, and deflected *a* in the reverse direction; here currents flowed in opposite directions out of both extremities of the wire.

154. The effects of induction enabled Werner Siemens and Faraday to explain the widely different velocities assigned by different experimenters to the electric current.

155. To pass through any conductor electricity requires time, the time being directly proportional to the length of the conductor.

156. But in the case of a submarine cable, another cause of retardation comes into play, namely, the charging of the cable; the retardation here is proportional to the square of the length of the cable.

Artificial Cables.

157. It was to illustrate points like these and to determine the dimensions to be given to the Atlantic cables, that Mr. Cromwell Varley devised his artificial cables.

158. In one of these cables a resistance equal to that of a real cable 14,000 miles in length is obtained by introducing into the path of the current feebly-conducting liquids instead of metallic wires. The inductive action is obtained by means of condensers of tin-foil. In another artificial cables coils of wire are employed to give the necessary resistance.

159. The arrangement described in Note 81 is a condenser. But those constructed by Mr. Varley are of enormously greater area, the condensing sheets being separated from each other not by plates of glass, but by thin sheets of paper and paraffine. The vastness of the

area and the proximity of the inducing surfaces combine to exalt the effect.

160. When the condensers themselves are charged by a battery, on discharging them they exhibit phenomena similar to those of a Leyden-jar. The shock, spark, and other effects of frictional electricity are readily obtained.

161. A series of fifty condensers, for example, joined "in cascade," that is to say, with the outer coating of each joined to the inner coating of the next, when charged with a battery of 1000 cells yield powerful sparks, and deflagrate wires.

162. If the wire be bent and introduced into a glass of water, the glass is shattered by the discharge.

163. In the 14,000-mile artificial cable are introduced a series of eleven tubes containing the resisting liquid. Into these dip wires. One end of the charging battery is connected with the earth, and the other end can, at will, be connected with the artificial cable. A series of ten galvanometers are placed between the resisting tubes along the artificial cable.

164. When no condensers are employed, on making connection with the battery, all the galvanometers appear to be simultaneously deflected.

165. When a condenser is introduced between each pair of resisting cells (ten condensers in all), the current has to charge each condenser to a certain degree before it can sensibly affect the galvanometer beyond the condenser. Hence, when the condensers are attached, the action on the galvanometers is successive, not contemporaneous.

166. Mr. Varley supposed his 14,000-mile artificial cable divided into sections representing stations in London, at Gibraltar, Malta, Suez, Aden, Bombay, Calcutta, Rangoon, Singapore, Java, and Australia. Supposing an actual cable laid, and galvanometers placed at these stations, the deflections obtained on establishing battery-contact would be successive; they are represented by the deflections of the galvanometers associated with the artificial cable.

167. By varying the resistance and the amount of inductive condenser-surface, a representation of any other cable may readily be produced.

168. Connected with the needle of each of the ten galvanometers is a reflecting mirror, from which a brilliant spot of light is cast upon a screen. When the cable is not in action, the ten spots form a row along the same vertical line; when the battery-contact is made, the successive deflections of the galvanometers are declared by the successive motion of the spots.

Sketch of Ohm's Theory and Kohlrausch's Verification.

169. I have already spoken (Note 110) of the force which urges forward the electric current (the electro-motive force). The amount of this force may be deduced from the action of the current, when opposed by different resistances upon a freely-suspended magnetic needle.

170. If the wire which carries the current be cut across, the current ceases to flow: the electricity ceases to be *dynamic*; but, at the two ends of the severed wire, we have *static* electricity.

171. By suitable instruments, the amount of this static charge may be determined; it increases with the number of elements of the battery.

172. It is, moreover, proportional to the strength of the current obtained when the wires are re-united.

173. In this way the static charge becomes a measure of dynamical action: electricity at rest is connected with electricity in motion.

174. In experiments on the electroscopic properties of the voltaic circuit, it is necessary that the battery should be well insulated.

175. If the middle point of a wire which connects the two poles of a voltaic battery be connected with the earth, the tension of that point is null. The circuit gradually rises in tension, right and left, to the two poles of the

battery; but on one side of the point we have exclusively positive electricity, while at the other side we have exclusively negative electricity.

176. At equal distances, at opposite sides of the zero-point, the tension is the same.

177. If any other point than the middle be connected at the earth, it becomes the zero-point, right and left of which, as before, we have the two opposite electricities.

178. If the negative end of the battery be connected with the earth, the whole wire shows positive electricity; if the positive end be connected with the earth, the whole wire shows negative electricity.

179. The wire offers a certain resistance to the passage of the current. The battery itself is also in the circuit; and the current has to overcome its resistance also. But the resistance of the battery may be expressed by a certain length of the external wire; when this is done, the sum of the lengths of both wires is called the *reduced length* of the circuit.

180. Given the reduced length of the circuit and the electro-motive force, we can determine, by a simple calculation, the electric tension of every point in the circuit.

181. The circuit through which the current flows may be represented by a horizontal line (called an abscissa); the electric tension at every point of the circuit may be represented by a vertical line (called an ordinate). If ordinates be drawn to represent the electric tensions at a great number of points of the circuit, the line joining the ends of all the perpendiculars will represent the distribution of electric tension in the circuit: the *steepness* of this line also represents what Ohm called the *electric fall*.

182. More strictly, the electric fall is the decrease in the length of the ordinate for the unit of length of the abscissa.

183. The total charge of the wire is expressed by the area of the triangle enclosed by the ordinate, abscissa, and line of fall.

184. The laws of the voltaic circuit, as enunciated by Ohm, have been verified everywhere. The electroscopic state of the circuit has been examined by Kohlrausch, and found to be in strict accordance with Ohm's theory.

185. Ohm assumed the passage of the electric fluid from one section to another of the connecting-wire to be due solely to the difference of electric tension between the two sections. He further assumed the quantity of electricity transmitted to be proportional to this difference of tension; and, from these fundamental assumptions, he deduced the laws of the voltaic circuit.

186. These laws may be briefly stated thus:—

(a). The strength of the current is directly proportional to the electro-motive force.

(b). The strength of the current is inversely proportional to the resistance.

(c). If the wire which unites the two poles of battery be of the same material, and of the same thickness throughout, the "electric fall" is the same throughout the wire.

(d). If the wire be of the same material, but of different thicknesses, the "fall" is steeper on the thin wire than on the thick; the "fall," and therefore the strength of the current, is inversely proportional to the cross-section of the wire.

(e). If the poles be connected by two wires of the same thickness, but of different resisting powers, the electric fall is steepest on the more resisting wire; the "fall" is directly proportional to the specific resistances of the wires.

187. In verifying these laws, Kohlrausch employed a condenser to augment the feeble charges obtained from his voltaic cell; and he held this instrument to be essential. By an exceedingly skilful device, Sir William Thomson has rendered the condenser necessary, and thus greatly simplified the means of demonstration.

CORRESPONDENCE.

THE METRIC SYSTEM.

To the Editor of the Chemical News.

SIR,—I am glad to see from your abstract of an article from the *Journal für Praktische Chemie*, that a plan for abbreviation of names of the metric system is proposed on something like authority. I should question, however, if the system there proposed will become general, as the use of capitals is inconvenient in writing, and is, so far as I remember, at variance with all our accepted abbreviations, as oz., lb., gr., &c.

My object in writing this letter is not to find fault, but to suggest that some recognised system, either the one referred to or some other, should be adopted in this country. It will not be long, I hope, before the metric system is made compulsory in England, and it is time that symbols for the different terms of the system were established.—I am, &c.,

Midland Institute,
June 4, 1870.

C. J. WOODWARD.

ELECTRO-COATING IRON WITH COPPER AND BRASS.

To the Editor of the Chemical News.

SIR,—The pithy and able notice of the above subject that you inserted in your report of the last meeting of the Chemical Society, will bear the following remarks from me which were made at the meeting.

The electrolytic brass bath consists of an aqueous solution of equal parts of ammoniac tartrate and potassic cyanide. After receiving cyanide of copper and cyanide of zinc in certain proportions, the oxides of the metals are added to the solution. If upon trial, this solution works with the evolution of hydrogen, a little of the blue ammoniuret of copper is added to the cold bath. The heat that may be used to this bath determines the colour of the brass, and may vary from 60° C. to nearly boiling-point.

The cast-iron calico-printing roll that was exhibited was coated with brass in a brass bath, then transferred to an acid copper bath (cupric sulphate) and coated with copper to 3-16ths of an inch thick.

The weight of the roller was 96 lbs., of the copper coating 29 lbs., and of the roller, when finished, 125 lbs.

The other specimens illustrated the deposition of yellow brass and a deep bronze from the same electrolytic bath.—I am, &c.

74, Brecknock Road, London, N.
June 2, 1870.

W. H. WALENN.

TETRABROMIDE OF CARBON.

To the Editor of the Chemical News.

SIR,—In the report of the Chemical Society's proceedings in the *CHEMICAL NEWS* (vol. xxi., p. 223), the following passage occurs:—

"In the above processes, terbromide of antimony may be substituted for the bromide of iodine."

The passage refers to the preparation of carbon tetrabromide. In the *CHEMICAL NEWS* (vol. xxi., p. 237), a letter appeared, designating this passage as erroneous; the correspondent expressed himself thus:—

"So far from our proposing the action of terbromide of antimony on carbon disulphide as a means of preparing tetrabromide of carbon, I am not aware that these two substances have any action upon one another at the temperature specified, 150° C."

Now, the paper on "Tetrabromide of Carbon," by T. Bolas and C. E. Groves, read by one of the authors at the Chemical Society's meeting on May 5th, contains *inter alia* the following:—

"(a). Two parts of carbon bisulphide, 14 parts dry bromine, and 3 parts iodine, were heated together, in a sealed tube, to a temperature of 150° C. for about 48 hours. The contents of, &c.

"(b). Antimony terbromide may be substituted for bromide of iodine in the above process. . . . The above reactions take place, although slowly, at 100° C."

I think there is no further comment required, except, perhaps, to remark that, had the correspondent in vol. xxi., p. 237, retained a copy of his scientific paper, he would have spared you much valuable space, and a little time and trouble too.—I am, &c.,

THE REPORTER.

June 7th, 1870.

MISCELLANEOUS.

Crystalline Alloy of Zinc and Calcium.*—The production of a crystalline alloy of zinc and calcium has been observed in the preparation of calcium by the process of M. Caron, in which an excess of zinc was employed. It contains about 95 per cent of zinc and 5 per cent calcium, corresponding to the formula $Zn_{19}Ca$. These crystals are small octohedrons with square bases. They are acted upon by water, with the liberation of hydrogen.—*Pogg. Annal.*

Illustrating the Gain in Weight of Burning Bodies.*—A very striking mode of demonstrating in the lecture-room that burning bodies increase in weight has been contrived by H. Kolbe. A glass rod is fastened, in a horizontal position, to one arm of a balance. Upon this is fastened a glass cylinder in which a candle is burnt, connected with which, by a glass tube, there is a V-tube for condensing the vapour, a flask filled with lime-water for carbonic anhydride, and two more U-tubes containing soda-lime. The last are connected, by an india-rubber tube, with a Bunsen's pump, by which a steady current of air is drawn through the apparatus. The beam is first counterpoised; as the candle burns away, the arm of the balance to which it is attached sinks down until its progress is arrested by the table.—*Ber. der. Berl. Chem. Gesellschaft.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, May 30, 1870.

Omitting the papers and memoirs relating to other branches of science, this number contains the following subject-matter bearing upon chemistry and collateral sciences:—

Physical Phenomena which Accompany the Bursting of Variably-Sized Hollow Projectiles (Bombshells and Grenades) by the Freezing of Water contained therein.—Ch. Mar-

* Communicated by Prof. Morton.

tins and G. Chancel.—The authors first refer at considerable length to the experiments made in this direction by different authors, from the earliest time up to the present day, and discuss the theories broached on this subject; they next relate their own experiments at length, from which they draw the following conclusions:—The bursting of hollow, cast-iron projectiles, by the effect of the freezing of the water contained therein, takes place when from 30 to 40 per cent of the water is converted into solid ice; this quantity of ice causes a pressure which reduces the total bulk by from 1.45th to 1.35th; the pressures required to cause the bursting for shells of 0.2 metre diameter vary from 430 to 590 atmospheres (each at 15 lbs. pressure to the square inch). This paper gave rise to a discussion, the speakers being General Morin, M. Dumas, and M. Elie de Beaumont, who stated substantially that since the properties of the metal are very much impaired by low temperatures, it would lead to erroneous conclusions to calculate, as the authors of the paper think can be done, the powder charges required for the bursting of projectiles; moreover, a very low temperature has been known to render cast-iron, steel, and wrought-iron so brittle, that it can then be readily reduced to powder.

Observations on the Melodious and Harmonic Intervals.—A. Cornu and E. Mercadier.—A paper on acoustics.

Reclamation of the Priority of the Discovery of Cyanic and Cyanuric Ethers.—S. Cloëz.—An abstract from various periodicals published since 1857, here quoted to prove the author's just claims to the honour of having discovered the bodies alluded to.

On Some Compounds Homologous of Tartaric and Malic Acids.—H. Gal and J. Gay-Lussac.—After referring to the labours of MM. Kekulé, Perkin, and Duppa, on this subject, the authors describe adipomalic, adipotartaric, suberomalic, and suberotartaric acids, obtained by a complicated process, described at great length—adipomalic acid, $C_{12}H_{10}O_{10}$; adipotartaric acid, $C_{12}H_{10}O_{10}$; suberomalic acid, $C_{16}H_{14}O_{10}$; suberotartaric acid, $C_{16}H_{14}O_{10}$. The authors exhibit, in a tabulated form, three groups, viz.:—Oxalic, malic, and tartaric groups, each made up of seven different compounds, some of which are, as yet, unknown, and have, therefore, only a hypothetical existence.

Action of Hydrochloric Acid upon Osseine; New Researches on the Estimation of Osseine in Fossil Bones.—A. Scheurer-Kestner.—From the author's researches it appears that osseine is soluble in concentrated hydrochloric acid in the cold, but is not acted upon by very weak acid; in order, therefore, to remove that acid, oxide of silver is employed by the author, and, on evaporating to dryness the neutral liquid thus obtained, a white residue is left, which, on ignition, emits the smell of burning horn, but this substance differs altogether from gelatine in its chemical as well as physical properties. The lengthy memoir contains several matters of interest for the determination of the geological age of fossil bones.

Rapidity of the Absorption of Oxide of Carbon by the Lungs.—N. Gréhaunt.—The contents of this paper are interesting to chemists, because the author states that, on heating the blood of persons poisoned with oxide of carbon with sulphuric acid to 100° , the gas alluded to is integrally evolved from the blood. The memoir is full of interesting physiological facts, as brought out by experiments.

Direct Preparation of Pyrotartaric Acid.—Dr. J. Sacc.—The author dissolves, by the aid of the heat of a water bath, 100 grms. of pulverised anhydrous tartaric acid in 100 grms. of acetic acid; the solution is next placed in a retort and heated over a charcoal fire, until the liquid becomes syrupy; on cooling, this thickish fluid deposits pyrotartaric acid in acicular-shaped crystals.

On Electric Currents; New Observations.—M. Tréve.

Phenomena of Electrostatic Induction.—J. Mario.

Theory of Electric Condensers.—M. Neyreneuf.

Description of a Hygrometer Acting by Absorption.—J. Séverin.

The Teacher of Descartes.—A. Georget.—The author, writing from Tours, states that Grandillon was in 1619 a student in a Jesuit college, and did not arrive as Divinity Professor at la Flèche before the year 1626, and that since Descartes had positively before that year left la Flèche, Grandillon cannot have been his teacher there.

Meteorological Observatory at Montsouris.—Sainte Claire-Déville.—The author presents to the meeting a report on this institution, and the labours performed there last year and during the early part of this year. The report contains a detailed description of the instruments employed.

Journal de Pharmacie et de Chimie, May, 1870.

This number contains the following original memoirs and papers:—

Thermo-Chemical Researches on the Bodies formed by Double Decomposition.—MM. Berthelot and Longuinne.—This very lengthy essay is sub-divided as follows:—Method of experimenting; acetic chloride, $C_2H_3ClO_2$; acetic bromide, $C_2H_3BrO_2$; acetic iodide, $C_2H_3IO_2$; butyric bromide, $C_4H_7BrO_2$; acetic anhydride, $(C_2H_3O_2)_2$. This essay is to be continued.

Some Experiments with Salts of Chromium.—A. Commaille.—It is to be regretted that this interesting paper is too lengthy for full translation, and is so written that it does not admit of any useful abstraction. It contains the following chapters:—Nitric acid and bichromate of potassa; sulphuric acid and bichromate of potassa; hydrochloric acid and bichromate of potassa; iodic acid and bichro-

mate of potassa; oxalic acid and bichromate of potassa; acetic, tartaric, citric, tannic, and benzoic acids, and bichromate of potassa.

Physical Method for the Determination of those Molecular Groups which are Decomposed by the Electric Current; Application to the Detection of Hydrates Dissolved in Water.—E. Bourgoïn.—This essay is divided into the following sections:—sulphuric acid; nitric acid; caustic potassa; sulphate of potassa; sulphate of soda.

Presence of Manganese in Milk and in Blood.—E. Pollacci.—The presence of manganese, as an essential constituent of milk and blood (human, as well as animal), has been known for about 20 years past, but the author gives in this paper some particulars about the method of detection of this metal in the two animal fluids referred to, of which milk contains this metal in the largest proportion; the milk is first evaporated (300 grms. are taken) to the consistency of a paste; this is carbonised by heat in a platinum crucible; the charcoal thus obtained is pulverised, and next completely incinerated; the ash is triturated in an agate mortar and lixiviated with water, in order to eliminate the salts soluble therein, especially chlorides; the residue is treated with very pure nitric acid, and the solution thus obtained is evaporated to dryness and calcined in a test tube; after cooling, a few drops of nitric acid are added, and the contents of the tube again boiled; next, a few grains of puce-coloured oxide of lead are added, and the liquid again boiled; a more or less deeply purplish coloured liquid appears on leaving the tube at rest for a short time, which is due to the formation of permanganic acid. No quantitative researches have, as yet, been made by the author.

Studies on Grapes; their Products and Vinification.—J. Le Canu.

Experiments on the Application of Tin-Foil for the Preservation of Perishable Substances.—E. Baudrimont.—This lengthy paper contains the record of a series of interesting experiments from which the author concludes that tin-foil, in consequence of its impermeability for water, may serve with great effect to protect various substances from the effects of the atmospheric moisture, as well as acting as a protective against the alterations fruit undergoes by evaporation of the fluids therein contained; tin-foil also protects against the oxidising action of the oxygen of the atmosphere, and may hence serve to keep fatty substances from becoming rancid; while, as proved by an experiment of the author, it may usefully serve in laboratories to wrap up caustic lime (quick-lime), bisulphate of soda, and similar substances, which may thus be preserved for a great length of time without deterioration.

Metallic Iron obtained by the Electric Current.—C. Collas.—The author employs a weak solution of chloride of iron, which is decomposed by the aid of a Bunsen battery; perfectly pure iron is thus obtained, which is very friable, highly oxidisable, especially when moisture is present; when this iron, in the state of fine powder, is poured in a bottle, when the atmosphere is very moist, the iron is instantaneously oxidised, water decomposed, and the evolution of hydrogen causes the bursting of the bottle.

Annales de Chimie et de Physique, April, 1870.

This number contains the following original papers and memoirs:—

Experimental and Theoretical Researches on the Equilibrium Figures of a Liquid Mass considered as having no Weight.—J. Plateau.—The 9th to 12th series of this lengthy memoir.

Researches on the Different Varieties of Carbon.—M. Berthelot.—This very extensive memoir is divided into the following sections:—General introduction; description of method for the immediate analysis of the divers varieties of carbon; researches on graphitic oxides; conversion of the same into ordinary organic compounds; investigation of the present state (*état actuel*) of carbon; relation existing between the graphitic compounds and organic substances properly so called; influence of various reagents upon carbon.

Oxidation of the Hydrocarbons.—M. Berthelot.—The main gist of this paper is that the author has found that several hydrocarbons can be directly oxidised without loss of any carbon, and form neutral substances such as aldehydes; this oxidation is effected by chromic acid, dissolved in a small quantity of water: pure ethylen is slowly acted upon, aldehyde being formed— $C_2H_4 + O_2 = C_2H_4O_2$; this reaction requires a temperature of 120° ; propylen is oxidised at the ordinary temperature— $C_3H_6 + O_2 = C_3H_6O_2$; acetylen is also acted upon at the ordinary temperature— $C_2H_2 + O_2 = C_2H_2O_2$.

Synthesis of Phenol.—M. Berthelot.—The contents of this paper have been already quoted from another periodical.

Action of Potassa on the Sulphuric Derivatives of the Hydrocarbons.—M. Berthelot.—The reactions which hydrate of potassa effects with the sulphuric derivatives of the hydrocarbons, no matter which, may be expressed by the following schematic formula:—Being given an acid,

basic; that acid, treated with potassa, forms a carbide—

Synthesis of Acetic Acid by Means of Acetylen.—M. Berthelot.—The author heats protochloride of acetylen with solution of caustic

potassa in alcohol to 100°, for 10 hours, and thus obtains a large quantity of acetic acid—

that is to say, $C_4H_2Cl_4 + 2H_2O_2 - 2HCl = C_4H_3O_4, H_2O_2 = C_4H_3O_4$; per-chloride of acetylen yields, under similar conditions, glycolic acid—

that is to say, $C_4H_2Cl_4 + 3H_2O_2 - 4HCl = C_4H_3O_4, H_2O_2 = C_4H_3O_4$; treated with aqueous solution of potassa this substance yields oxalic acid— $C_4H_3O_4$.

Polytechnisches Journal von Dingler, first number for April, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

On Naphthylamine Violet.—Dr. A. Kiellmeyer.—From this lengthy paper we learn that the author has investigated this subject thoroughly, and his chief result is that pure naphthylamine yields a fast violet on cotton, if applied in the following manner:—Take starch, 456 grms.; water, 1½ litre; dry naphthylamine, 118 grms.; water, 1½ litre; pure hydrochloric acid, sp. gr. 1.1279 grms. Boil this mixture, and add, after cooling—chlorate of potassa, 13½ grms.; water, 0.3 litre; this compound is printed on, and, after printing, first treated (aged) as is done for aniline black, and next passed through a solution of soda, in order to eliminate the hydrochloric acid set free after that operation and thorough washing, a pure, fast, brilliant violet is obtained.

Detection of Madder Colours upon Cloth, and by Themselves.—Dr. W. Stein.—The author boils the cloth with a concentrated solution of sulphate of alumina, whereby a liquid is obtained of reddish colour, exhibiting a golden-greenish fluorescence, due, the author says, to the presence of purpura; the behaviour of the colouring matters of madder towards sulphate of alumina is, says the author, so characteristic, that that salt may serve as an effective test for these substances; the alizarine may be readily rendered soluble by treating the dye material or dyed cloths with alcohol acidified with hydrochloric acid.

Extraction of Beet-Root Juice, and its Defecation and Clearing by Means of Sulphuric Acid, Sulphite of Lime, Lime, and Alcohol, as Experimentally carried on at the Beet-Root Sugar Works at Marly, near Valenciennes, France.—MM. Duquesne and Gil.

On Duoline, a New Kind of Blasting Powder.—C. Dittmar.—Duoline is a mixture of cellulose, nitro-cellulose, nitro-starch, nitro-mannite, and nitroglycerine, in various proportions; it is from four to ten times stronger than ordinary powder.

Aniline Black for Linen.—Dr. Dingler.—The linen fabric is well shaken in a bath containing a solution of acetate of aniline at 4° Baumé (sp. gr. 1.029); this bath should contain besides—sal-ammoniac, 4 per cent; chlorate of potassa, 4 per cent; nitric acid, 4 per cent; sulphate of copper, 1 per cent. After the textile fabric has been aged for about three days, it is first passed through a liquid bath, containing ammonia, at 60°, and next washed in a weak soap solution. A very beautiful black is produced.

First May number, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Electrical Clock.—Dr. Arzberger.—With several illustrations.

Metallic Thermometer.—C. Oechsle.—With woodcuts.

Manufacture of Cast-Steel from Pig-Iron, by What is Termed Inter-Molecular Combustion.—S. Jordan.

Graduation of Oil Testers (Areometers).—Dr. G. Th. Gerlach.

Detection of, and on the Injurious Action of, the Vapours of Acetic Acid Mixed with the Air in Some Manufacturing Processes.—Dr. P. Bolley.—By means of apparatus (not specified), the author found that a cubic metre of air in a calico printing-room, where the ventilation was good, amounted to 75 decigrammes, while, with bad ventilation, as much as 15 decigrammes per cubic metre were detected. The author enters at length into details on the injurious effect of these vapours upon the workmen.

Manufacture of Naphthylamine.—M. Bällo.—The author treats nitro-naphthaline with iron and acetic acid, and distils by means of steam; from the distillate the base deposits, on cooling, in crystals.

Revivification of Animal Charcoal by Means of Brüdenwasser.—Dr. O. Tech.—By Brüdenwasser is understood the water occurring near Sojsic, in Bohemia; this water contains from 0.013 to 0.026, and sometimes even 0.5 per cent of ammonia.

Annalen der Chemie und Pharmacie, April 1870.

This number contains the following original memoirs and papers:—

Researches on the Salicin Derivatives.—H. Schiff.—This very lengthy essay contains the following subdivisions—Artificial formation of populine; acetosalicine; preparation of helicine, helicoidine, and nitrosalicylic acid; acetyl and benzoyl-helicine; acetohelicoidine; anilide and toluide of salicylglycoside.

Sulpho-urea from Persulphocyanic Acid.—L. Glutz.

Persulphocyanic Acid Aniline.—L. Glutz.

Pseudosulphocyanogen.—L. Glutz.

On Some of the Sulpho-Acids of Benzyl.—Dr. O. Böhrer.—This lengthy paper contains the following sections:—Benzylsulpho acid; nitrobenzylsulpho acid; monochlorobenzylsulpho acid.

On a Compound of Essential Oil of Mustard with Bisulphate of Potassa.—Dr. O. Bühler.—After briefly stating that essential oil of mustard—

combines directly with several substances, as, for instance, ammonia, sulphide of potassium, and organic bases, the author states that he discovered the compound alluded to—

Percentically:—Carbon, 22.01; nitrogen, 6.42; sulphur, 29.55; hydrogen, 2.30; potassium, 17.18; oxygen, 21.91.

Phenylsulphopropionic Acid, a Derivative from Cinnamic Acid.—C. Varlet.

On Some Compounds of Benzol-Aldehyde, and Primary Monamides.—Dr. E. Roth.

Chlorocumarine.—Dr. H. Bäcksecke.

Mercurodiphenyl.—E. Dreher and R. Otto.—Mercurodiphenyl is a crystalline material, readily soluble in chloroform, benzol, sulphide of carbon; difficultly so in ether and alcohol; fuses at 120°; sublimes without decomposition; formula— $C_{12}H_{10}Hg$. The authors treat also of the action of hydrochloric, hydriodic, and sulphuric acids, on this material; its behaviour at higher temperature; action of sulphur upon mercurodiphenyl; action of bromine upon mercurodiphenyl; action of chlorine upon this substance; formation of mercuromonophenylchloride from mercuric chloride and mercurodiphenyl; action of hypochlorous acid upon mercurodiphenyl; behaviour of

and nascent hydrogen; acetomercuromonophenyl,

formic and propionic mercuromonophenyl; behaviour of acetomercurodiphenyl with hydrochloric and sulphuric acids; behaviour of acetomercuromonophenyl towards nascent hydrogen; action of hydrosulphide of ammonium and sulphuretted hydrogen upon acetomercuromonophenyl; behaviour of the last-named body at a high temperature; experiments for the purpose of preparing nitrated mercurodiphenyl; preparation of oxymercurodiphenyl; preparation of phenyl ether by the action of Cl_2O upon mercurodiphenyl; action of bromethylen upon mercurodiphenyl; preparation of zinc-diphenyl; copper and iron diphenyl from mercurodiphenyl.

Direct Conversion of the Fermentation Butyl-Iodide into Trimethyl Carbinol and its Acetic Ether.—E. Linnemann.

Notice Concerning the Derivation of the Law of Avogadro.—K. Zöppritsch.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, March, 1870 (No. 207).

This number does not contain any papers or memoirs relating to chemistry or collateral sciences.

Revue des Cours Scientifiques de la France et de l'Etranger, No. 25, 1870.

This number contains:—

Shape of Comets.—Dr. Faye.—A lengthy lecture read on this subject at the Sorbonne, and published with a series of diagrams and cuts.

Asphyxia Produced by the Fumes of Charcoal.—Dr. C. Bernard.—The instalment of this lengthy lecture on this subject, here published, contains the full and exhaustive description of the chemical and histological alterations the blood globules undergo by the action upon them of carbonic oxide and carbonic acid, and the result arrived at by the eminent author is that the asphyxia alluded to is purely due to physico-chemical alterations of the globules aforesaid.

Moniteur Scientifique, No. 322, May 15, 1870.

This number contains:—

The Increasing Expense of Living.—G. Ville.—The continuation and end of this lengthy paper, for which see *CHEMICAL NEWS*, vol. xxi. p. 215.

Although not exactly belonging to the subjects treated of by us, we quote the title of:—

Use of Contre-Vapeur (Steam Backing) in Locomotive Engines Attached to Trains.—A. N.—A very useful and well written paper on this important subject.

Among the *brevets d'invention* we notice:—

Manufacture on the Large Scale of Nitrate of Ammonia by the Action of Electricity upon a Mixture of Air and Steam.—F. A. A. Dufournel.—The eminent editor of this periodical points out very properly, that what is possible as a laboratory experiment will not pay to do on the large scale.

Tinning of Iron Without the Aid of Heat.—J. B. A. Daubié.—The chief point of interest in this matter is, that the tinning of iron in the cold cannot succeed at all, unless the bath used for that purpose contains, in solution or suspended, an organic substance like starch or glucose, although no precise scientific explanation of this indispensable condition has been hitherto given; the *breveté* employs the following bath—To 100 litres of water are added 3 kilos. of rye meal; this mixture is boiled for half an hour, and next filtered through cloth; to the clear but thickish liquid are added 106 kilos. of pyrophosphate of soda, 17 kilos. of protochloride of tin in crystals (so called tin-salt), 67 kilos. of neutral protochloride of tin, 100 to 120 grms. of sulphuric acid; this liquid is placed in well made wooden troughs, and serves more especially for the tinning of iron and steel wire (previously polished) for the use of carding machines. When instead of the two salts of tin just named cyanide of silver and cyanide of potassium are taken, the iron is perfectly silvered.

New and Improved System for the Manufacture of Fuming Sulphuric Acid.—H. Schemfil.—While the fuming sulphuric acid made at Nordhausen, in Saxony, from previously desiccated sulphate of protoxide of iron, is sold there at from 8 to 12 francs the 100 kilos., that acid as manufactured in France, from an anhydrous bisulphate of soda or potassa, costs from 100 to 140 francs per 100 kilos. The author's plan is to convert iron pyrites, by an expeditious and cheap process, into dehydrated sulphate of iron, and to obtain from this fuming sulphuric acid by a continuous process, the particulars of which cannot be detailed without reproduction of the engravings of the kilns and furnaces devised by the *breveté*, and which are of a very peculiar make.

Les Mondes, May 19, 1870.

Climate of the Haute Savoie.—Rev. Vaullet.—The author, residing at Annecy, states that he can prove that the mean temperature of the Département of France just named, has perceptibly and steadily increased within the last forty years from 8° to about 10½°; as proof of this statement, he points out that the cultivation of wheat and vineyards is now possible and successful in localities where it was not so forty years ago. Among the causes the author enumerates the cutting down of forests, draining of marsh lands, improvement of roads, and the bringing under tillage of moor and waste lands.

Effects of the Colouration of the Water of the Mediterranean.—J. Girard.—According to the author, who has made several journeys on this large inland sea, its peculiar colour, ranging from pale blue, through all shades of that colour to black (viz., when seen from a ship's deck), is entirely due to the mode of reflection of the sun's rays, according to the lower or higher position of that luminary above the horizon, so that at mornings and evenings, when the rays fall more obliquely, and pass therefore through a larger bulk of water, the colour is deepest, viz., at such distances from the shore where the depth of the sea is sufficiently great.

Discovery of Phosphate of Lime near Charlestown, U.S.—According to the contents of a letter received by the editor of this periodical, there has been recently discovered a layer of a very pure phosphorite, averaging in thickness from 0.40 to 0.60 metre, over a surface of some 250 hectares; this mineral is used as manure by itself, after having been simply ground up to a fine powder.

Annales du Génie Civil, May, 1870.

This number contains a very lengthy paper on—

Soap and Soap Making.—L. Droux.—This paper is far too lengthy for any useful abstraction; it contains copious results of analyses of all kinds of soaps, and also full details on its adulterations.

Annales des Mines, No. 2, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Extraction of Lead from its Ores, by means of a Reverberatory Furnace, as carried on at the Works of the Nouvelle Montagne Company, at Engis (Belgium).—V. Bouhy.

Mineral Resources of the Arège.—M. Mussy.—Second paper on this subject.

Mechanical Properties of Steel which contains Phosphorus.—L. Grüner.—When phosphorus is present in quantities of from 0.002 to 0.003, it renders steel more elastic and rigid, increases its resistance to breaking force, without modifying its hardness; but such a steel, even if it contains only little carbon, is wanting in body, and is cold-short.

Archives des Sciences Physiques et Naturelles, Suisses, May 15, 1870.
This number contains the following original papers relating to chemistry and collateral sciences:—

Determination of the Coefficient of Expansion of a Bar of Silver.—E. Plantamour and A. Hirsch.

Description of a New Method for Estimating the Caloric Capacity of Fluids.—E. Wartmann.

Remarks on a Memoir on the Specific Gravity of Ozone, published by M. O. Wolfenstein.—J. L. Soret.

Cosmos, June 4, 1870.

General Assembly of the Association Polytechnique.—This meeting was held on the 29th of May last, under the presidency of M. J. Dumas, Sénateur, &c. This Association has been established for the purpose of giving to the working classes the opportunity of becoming acquainted with physical and other sciences, by means of lectures methodically given, to the number of 200 weekly per annum. Some 20,000 workmen attended last year; and the eminent chairman was authorised by the French Government to communicate to the meeting that this Association is recognised as an establishment of public utility.

Serious Illness of Professor Liebig.—V. Meunier.—From a short notice taken from a daily paper, it appears that the celebrated *savant* just named has been seriously ill for some time, having had to undergo twice a dangerous operation on an abscess at the neck. The patient is very feeble, and is stated to have said that he does not believe he will ever recover.

Decrease of the Rainfall in France.—S. Meunier.—The author states that it appears more and more certain that the annual quantity of rain is rapidly decreasing; the cause is attributed to the cutting down of forests, and to the fact that no sufficient care is taken to keep the mountains well covered with suitable vegetation, so as to enable their soil to grow trees in abundance.

NOTES AND QUERIES.

Tungsten Blue.—A sample made by the process given in vol. xxi, p. 130, of our journal, has been sent to our office for T. W. S. If he will forward his address we will send it by post.

Bauxite.—Can any of your readers inform me where I can purchase the bauxite referred to in vol. iii, p. 203, of "Kerl's Metallurgy." It is composed of 13 to 17 per cent of silica, 60 to 65 per cent of alumina, 4 to 8 per cent of peroxide of iron, and 15 to 17 per cent of water in combination.—J. B. S.

Self-Raising Flour.—(Reply to "B.S.")—We cannot say for certain, not having had any opportunity of investigating this subject, but it is possible that a small quantity of either dried yeast or, perhaps, good malt powder, is mixed with the material you allude to; both would have the effect of making the flour self-raising upon its being mixed with water.

Phosphate of Ammonia.—(Reply to "J. W. M.")—You cannot make this salt direct from bone ash; you will have to extract the phosphoric acid from that substance, and then combine it with ammonia.

Oxygenated Water.—(Reply to "J. C.")—The process is patented; you can learn at the Patent Office the particulars you desire, and also whether the patent has expired.

Chrome-Colour.—The periodical referred to may be inspected at the Library of the Commissioners of Patents, where you will also find vol. xxi. of *Poggendorff's Annalen*, where, at p. 580, is to be found a full description of Liebig's and Wöhler's process for the preparation of a vermilion-red chrome-colour, for which we also refer you to Gentile's "Lehrbuch der Farben Fabrikation," to be found in the same library.

MEETINGS FOR THE WEEK.

MONDAY, June 13th.—London Institution, 4.
Geographical, 8.30.
TUESDAY, 14th.—Photographic, 8.
WEDNESDAY, 15th.—Meteorological, 7. Anniversary.
THURSDAY, 16th.—Royal, 8.30.
Zoological, 4.
Chemical, 8.

TO CORRESPONDENTS.

A Young Subscriber.—1. Chloride of nitrogen or a similar chloride.
2. Your explanation is probably correct.

J. C. Major.—Apply to Asher and Co., Bedford Street, Covent Garden. We do not know the price for single numbers.

John E. Williamson, in asking a question, desires us to send the reply to his address, as he does not see the *CHEMICAL NEWS*. Surely we are not expected to supply information to those whose interest in chemistry is not sufficient to purchase a copy of our journal. If our opinion is worth anything, it is surely worth fourpence! At all events our time is too valuable to write private letters to such correspondents.

C. J. W.—Reinsch's test is the most practically useful for your purpose.

J. Cox.—There are several large works in German, but amongst the smaller works one of the most perfect and comprehensive is Wöhler's "Lehrbuch der Anorganischen und Organischen Chemie," 2 vols., 8vo., published at Berlin by Dünker.

R. W. W.—We know of no one we can recommend.

Dr. R. Gerstl, C. H. Wood, and John Pattinson, are thanked for their communications.

THE CHEMICAL NEWS.

VOL. XXI. No. 551.

ON THE DESCENT OF GLACIERS.*

By The Rev. HENRY MOSELEY, M.A., F.R.S.,
Canon of Bristol, and Instit. Imp. Sci. Paris Corresp.

GLACIERS do not take their origin in the highest Alpine regions. It is not there that the snow chiefly falls, but on a belt girding them below. This wide belt is divided horizontally into an upper and lower part by the snow-line, at a height of from 3000 to 3300 yards. Above that line snow always lies, and rain very rarely falls; beneath the snow-line the snow disappears every summer, and rains are abundant. It is from this belt about the snow-line that the glaciers are seen emerging. They lie like huge slugs along the descending valleys, swelling themselves out to fill their channels where they are wide, and thinning themselves to pass through the gorges and narrow places in them. They seldom come down to a lower level than 1100 yards. Between this level where they end and the snow-line, 3100 yards high, where they begin, they traverse sometimes a very long space—lying for the most part at a low pitch. The resemblance to a huge mollusk is kept up in this, that they move with a strange slow motion, not altogether unlike that of such an animal. The parallel will be complete if we conceive the mollusk to have its tail continually renewed as it withdraws it from under the snow-line, and its head continually melted away as it thrusts it forward below the level of from 1000 to 1400 yards. If we further imagine the steep sides of the valley through which the glacier descends to have similar but smaller glaciers crawling down them to the principal glacier, we shall understand what is meant by tributary or secondary glaciers, which are thus placed in regard to the principal ones; having a far greater pitch or slope than they, and flowing into them like tributary streams to a river. The slope of a principal glacier is often as little as 3° , and yet it may move with a velocity of 24 inches a-day. The slope of a tributary glacier is sometimes 50° , and it may not advance more than 4 or 5 inches a-day at the most.† Masses of rock of different sizes, from huge boulders to stones, are constantly broken by the frost from the sides of the valley of the glacier, and are carried slowly down on its back to the level where its head melts away, and there are deposited. These are called moraines. They lie along the course of the glacier in ridges, protecting the ice beneath them from the sun's rays. That ice does not therefore melt as the rest of the ice does, and so it forms a ridge of ice. A moraine is, therefore, a ridge of stones standing on a ridge of ice.

The descent of a glacier is not a descent of the whole together, or bodily like that of a block of stone. There is an internal descent of every particle in the glacier over and alongside of every other particle. If a plane section be imagined to be made across it, the particles of ice passing through that cross-section at any time must be conceived to be all moving at different rates so as to be sliding over and beside one another; the particles at the surface moving faster than those below, and the particles near the centre moving faster than those at a distance from it, exactly as the particles of a stream of water move.

The existence of this differential motion is strikingly seen in what is called the veined structure of glaciers. This veined structure appears first to have been described by M. Guyot, in the year 1838. The following is his account of it, as he saw it on the glacier of Gries, which I translate from the work of M. Huber:—

"I saw under my feet the entire surface of the glacier covered with furrows an inch or two wide, cut in snowy ice, and separated from one another by ridges of harder and more transparent ice. It was evident that the mass of the glacier was here formed of these two different kinds of ice; the former (that of the furrows) was white and melted more rapidly; the other (that of the ridges) was more perfect, crystallised, transparent, and hard. The unequal resistance to melting of these two kinds of ice was the obvious cause of these depressions and elevations. After having followed them for several hundreds of metres I reached a crevasse 20 or 30 feet wide, which, cutting the furrows at right angles, exhibited down to the depth of 30 or 40 feet an admirable transverse section of this structure. As far as my eye could reach I saw the mass of the glacier composed of layers of the [opaque] white ice separated from one another by layers of the transparent ice, the whole forming a mass as regularly stratified as certain calcareous rocks." This is the veined structure of glaciers.

[Canon Moseley's remarks on the differential motion of glaciers, with special reference to the observations and experiments of Forbes and Tyndall, illustrated by diagrams, will be found in the *Philosophical Magazine* for April, 1870.]

The effect of the differential motion in separating and distributing the parts of a glacier has been shown in various ways. The remains of the guides lost in 1820 in Dr. Hamel's attempt to ascend Mont Blanc were found imbedded in the ice of the Glacier des Bossons in 1863. "The men and their things were torn to pieces and widely separated, many feet. All around them the ice was covered in every direction for 20 or 30 feet with the hair of one knapsack spread over an area three or four hundred times greater than that of the knapsack." "This," says Mr. Cowell, from whose paper read before the Alpine Club in April, 1864, I have made the quotation, "is not an isolated example of the scattering that takes place in or on a glacier; for I have myself seen on the Glacier of Theodule the remains of the syndic of Val Tournache scattered over a space of several acres."

Whatever the force may be which causes the descent of glaciers, it must be chiefly expended in this constant displacement of the particles of the ice over one another and alongside one another, of which the veined structure affords the evidence, and to which is opposed everywhere that force of resistance which is called *shearing force*. By the property of ice called regelation, when any surface of ice so sheared is brought into contact with another similar surface, it unites with it, so as to form of the two one continuous mass. This may be shown by experiment. If a cylinder of ice be placed in an apparatus suitable for the purpose and slowly sheared partly across, the new surfaces continually being brought in contact with one another in the act of shearing will not present the slightest appearance of separation, the ice being there as continuous as elsewhere, its molecules entering into precisely the same relations to one another in their new positions as they did in the positions out of which they have been sheared. Thus a slow displacement of shearing, by which different similar surfaces of ice in a glacier were continually being brought into presence and contact with one another, would exhibit all the phenomena of the motion of glacier ice.

The late Principal Forbes calculated that in the Aar glacier the shearing displacement amounts to 13-14ths of the whole displacement of the glacier. The sliding displacement of the whole glacier bodily on its bed is, in comparison with it, unimportant as it regards the expenditure of force requisite to bring it about. The differential

* Read before the Royal Institution of Great Britain, Friday, May 13, 1870.

† The motion of the Glnberg, a tributary of the Aar glacier, inclined at 30° to 50° , was found by Desor to be 22 metres a year, while that of the Aar glacier, inclined at 4° , was 77 metres

motion is the *great and characteristic* phenomenon of the descent of glaciers; but it is that, in assigning an adequate cause for which, existing glacier theories seem to me most conspicuously to have failed.

The Swiss philosopher De Saussure was the first to study the descent of glaciers with care, and wrote on it about sixty years ago. He held that glaciers slip down the slopes on which they rest by their weight, just as other bodies slip down inclined planes. This explanation is simple, and was generally accepted as long as it was thought that glaciers slipped down bodily like blocks of stone would, with an equal motion of all their particles; but when the internal motion of their particles upon one another, like that of running water, came to be discovered, and when it was found that the high-pitched tributary glaciers moved slower than the low-pitched principal ones, this theory was brought into doubt, for it was in direct contradiction to these facts.

M. Rendu, the Bishop of Annecy, considered the descent of a glacier to be so like that of a fluid that it was impossible to explain it otherwise than by supposing ice actually *to be a fluid* and not the *solid* thing it seems to be. He was the founder of the celebrated viscous theory of the descent of glaciers, advocated with such remarkable energy, industry, and ability by the late Principal James Forbes, whose various works on glaciers have exhausted the whole field of observation and supply most of the facts on which the true solution of the problem, whenever it is arrived at, must be founded. When, however, at another stage of the inquiry, it came to be discovered by Faraday and Tyndall that ice, when broken up, was capable of being united again by sufficient pressure, so as to become as perfectly solid and homogeneous as it was before, it became evident that supposing a sufficient pressure to be exerted on the glacier, in the direction of its descent, to crush its substance through the contractions and gorges of its channel, and over the irregularities in its bed, it would reform itself and solidify, and become a compact mass again as it was before, when it had passed these obstructions. This is the *regelation* theory.

At this stage the question had assumed this new form—"If ice be a viscous fluid, according to the viscous theory, is it fluid *enough* to descend by its own weight; or, if it be a solid, according to the *regelation* theory, is it *little enough* solid so to descend?"

If, instead of ice, a glacier were of water, it *would* obviously descend by its weight. The same would be true if it were of oil, or soft mud, or quicksilver, or probably of pitch; but if it were of iron, or of copper, or of lead, it would not descend by its weight only, unless, indeed, these metals were in a state of fusion. A quicksilver glacier would descend by its weight only because it shears easily; a cast-iron one would not, because it shears with difficulty. There must, therefore, exist a relation between the shearing force and the weight of a given volume of a glacier, so that it may just descend by its weight only. Now, it is possible to investigate mathematically what that relation is.

I have made that investigation.* I have founded it on this well-known law of mechanical philosophy, that "The aggregate *work* of the forces which produce the displacement of a body or a system of bodies (however related) must, at least, equal the aggregate work of the resistances which oppose that displacement."

The resistances opposed to the displacement of a glacier are—1. Those which oppose themselves to the shearing of one surface of ice over another, which is continually taking place throughout the whole mass by reason of the differential motion. 2. The friction of the superimposed laminae of ice upon one another, which is greater in the lower than the upper. 3. Abrasion of the ice on the bottom and sides of the channel of the glacier. If it descends by its weight only, then the work of its weight in its descent through any distance must at least equal the sum of the works of all these resistances. It is, of

course, impossible to represent this relation mathematically in respect to an actual glacier having a variable direction and an irregular channel and slope; but in respect to an imaginary one having a constant direction and a uniform channel and slope, it is possible. I have made that calculation, and it results from it that the unit of shear in ice (that is, the force necessary to make one square inch of ice shear over another square inch) must not be more than $1\frac{1}{4}$ lb. that a glacier may descend by its weight only. If the unit of shear in ice be more than that, then the glacier cannot descend by its weight only on a slope like that of the Mer de Glace. But it is a great deal more than that. It requires from 60 lbs. to 120 lbs. to shear one square inch of ice over another square inch. The ice of the Mer de Glace cannot, therefore, descend by its weight only; it does not shear easily enough. It must be ice of about the consistency of soft putty to descend by its weight only, for that substance shears with a pressure of from $1\frac{1}{4}$ lbs. to 3 lbs. per square inch.

Ice, therefore, if it be fluid, is not fluid *enough*, and if it be solid, it is *too* solid to descend by its weight only. There must be some other force to help it down besides its weight—certainly forty-five times greater, and possibly ninety times. The imaginary case, to which alone these calculations apply, differs, indeed, from the actual case of a glacier in this respect, that it is straight and uniform. But if its weight be insufficient to bring a glacier down a straight and uniform channel, much more will it be so to bring it down a crooked and variable one. This result is directly opposed to the viscous theory and to that known as the theory of regelation, both of which attribute the descent of glaciers to their weight as the only cause. It reveals the existence of some other force. What is it?

(To be continued.)

ANALYSIS OF THE KHETTREE METEORITE, WITH AN ACCOUNT OF ITS FALL.

By D. WALDIE, F.C.S.

THE meteoric stone, of which the analysis is given in the following pages, fell near Khettree, Rajputana; and the sample was supplied to me by Mr. W. Stotesbury, of the Topographical Survey, who at the same time communicated an interesting account of the circumstances of the fall, of which he was to some extent personally cognisant. The account I shall give in his own words, from his letter to me.

"Whilst employed in making a topographical survey of a portion of Shekawattie, in Rajputana, in February, 1867 (I forget the exact date),* I was out at work one morning at about 9 o'clock. I was suddenly startled by a loud report, resembling that of a cannon, at Khettree, the seat of a petty prince, about 11 miles distant to the south of the place where I was then working. The first report was followed by two more, louder than the first, but a little to the east of the place where I imagined I heard the first report; these three were succeeded by a regular roll, resembling musketry heard at a short distance. The day being a beautiful bright one, and no clouds to be seen anywhere, and also seeing no stones falling, I did not know what to make of this (to me) strange atmospheric phenomenon. I immediately communicated the above facts to the Editor of the *Delhi Gazette*, asking to know what these strange reports in the air meant, and the cause thereof. The day after I had posted the letter, I was informed by some villagers that, the day before, they heard the reports, and that a shower of aërolites had fallen, and that the stones had been seen by them. Mr. Robert Todd, a friend of mine, and in the same survey-

* Mr. Stotesbury has since found, from an entry in one of his books, that the date was January 19th, 1867.

* *Phil. Mag.*, May, 1869.

party as myself, seeing my query in the *Delhi Gazette* regarding these reports, wrote to the Editor of the above paper, informing him that they were caused by a fall of aërolites: he was at that time working about 10 miles to the east of me, and describes the reports, &c., the same as I have mentioned already. The showers of stones, as I learned afterwards from the villagers, amounted to about forty, which fell chiefly near a village called Saonlod, 3 miles to the north of Khettree, in Shekawattie, Rajputana (lat., $28^{\circ} 9' 45''$ N.; long., $75^{\circ} 51' 20''$ E.; and about 90 miles S.-W. of Goorgaon, near Delhi).

"The natives, not knowing what to make of these stones, and being just as superstitious as, if not more than, all natives of India, put it down the vengeance of some offended deity: they therefore set about gathering all the stones that they could find; these they afterwards pounded down to powder, and scattered this to the breeze, &c., so as not to let the vengeance of the offended god redound on them. No sooner did I hear of the fall of the stones, and ascertained the exact locality, than I sent all the Sowars attached to my camp to scour the country round about the place, with the intention of procuring as many of the stones as possible. I was very nearly too late; as, between them all, they only managed to get the piece I sent down to you, and that by a promise of a large reward. I cannot fully describe to you the fear of the inhabitants of the villages adjacent to where the stones fell, and their amusing and queer descriptions as to their ideas of the cause and nature of the aërolites.

"I am sorry I had not an opportunity of viewing one of the stones before they had been broken by the foolish villagers; as I should have then been able to give you the real size, &c., of them; but, from descriptions given me by the more respectable class of natives, I should say the stones were about the size of a 24-pounder shot, quite round, with a blackish appearance on the outside, and impregnated with a sulphurous smell. They fell with such velocity that they sank 2 or 3 feet into the ground, a sandy soil. The men who gave me these descriptions I summoned and questioned them myself. Of course, as is natural with natives, I received all sorts of communications regarding the fall of the stones; but they are only as foolish as they are untruthful, so it is no use my giving them you. The descriptions I have now given you may be relied on, as they are collected, by myself, from personal interviews with the more informed and respectable class of natives, such as Mahajans, Pataels, and the Raj officials; and I only kept those descriptions that tallied with others I had previously received from others."

The stone is partly of a light bluish grey colour, partly of a much darker grey; in some places the two portions lying in contact like two strata, in others nodules of the one imbedded in the other. The broken surface is studded over with metallic particles, many of them having a bright metallic lustre; and there are also observable, by aid of a lens, spots of a yellowish or brown colour, from oxidation of the iron, and granules of a greenish-yellow colour and translucent appearance, probably olivine. Spherules of earthy matter are also visible, and round cavities in which others have been imbedded. When coarsely powdered, the spherules are more visible; and, when more finely powdered and examined under water with the lens, the lighter portion of the stone exhibits a considerable quantity of a nearly white crystalline matter, the particles of which are tolerably uniform in size, mixed with small angular fragments of black, brownish, opaque, and greenish-yellow, translucent minerals, and irregularly-shaped but rounded particles of iron. The dark grey portion exhibits the same appearances, but with a much larger proportion of dark-coloured, earthy minerals. The particles of the iron, having resisted trituration, now appear much larger than the others. After the metallic matter has been removed by acid, the remainder seems to consist of the white, fine, crystalline matter observed in the original light grey portion of the stone, mixed with a few

black particles. The stone is not very hard, and, but for the particles of iron, is not difficult to powder.

It is covered with a dark grey, nearly black crust, cellular on the surface, and corrugated somewhat longitudinally, and of about one-third of a millimetre thick.

Many of the older analyses of meteorites are very imperfect, being very defective even in the detection and estimation of the chemical constituents. Of late, the chemical examination has been much more complete, and improvements have been made in their proximate analysis, obviously a matter of the greatest interest. The most recent of these investigations have been the very valuable ones by Daubrée and Meunier, of the Museum of Paris, chiefly on meteoric iron, for the separation of the uncombined metal from the sulphides and phosphides and other constituents. As my attention had not been previously directed towards the analyses of meteorites, I did not notice their papers so early as would have been desirable, and lost time and labour in the first processes employed. The separation of the earthy minerals is still very imperfect, and there are no very obvious means available for this purpose.

The general plan of analysis followed was to act upon the powdered stone first by acid solvents, and afterwards to extract the silica set free from combination by boiling with solution of carbonate of soda. The matter resisting the action of these agents was attacked in the usual way, by fusion with alkaline carbonate, or with baryta. The boiling with carbonate of soda was troublesome: the solution could not be filtered perfectly clear; it always carried with it a small portion of undecomposed mineral in a fine state of division.

The constituents were those generally found in meteoric stones of similar appearance. The part soluble in acids consisted chiefly of silicate of magnesia and iron, with interspersed particles of nickel, iron, and sulphide of iron. The part insoluble in acids was also chiefly silicate of magnesia and iron, but with a much larger proportion of silica.

The analysis of several different portions showed a certain variety of composition. Thus the insoluble matter varied from 39.5 to 42.6 per cent of the whole. In the soluble portion, the total amount of iron varied from 24.7 to 27.7 per cent in all states. As the particles of iron differ very considerably in size, it follows that, as the proportional quantity of these varies, so must that of the other constituents.

But treatment with acids did not show the amount of iron in the free state, as distinguished from that in combination; iodine answered better, but acted partially on the sulphide of iron, as well as on the uncombined metal. Recourse was had to the solvent lately proposed by Meunier—solution of bichloride of mercury, which dissolves the uncombined metal only: the mercurous chloride produced was removed by a current of chlorine, according to his plan, and metallic mercury by heat; the remaining mineral was then treated by hydrochloric acid, preferably with addition of some nitric acid. From the amount of iron found in this acid solution, a proportion was deducted as combined with the sulphur and phosphorus; the remainder was calculated as oxide. The sulphide of iron was taken as Fe_2S_3 , troilite, as contended for by Meunier. The whole of the nickel is supposed to be in the state of alloy with iron, though probably part exists as sulphide.

An attempt was made to separate the light-coloured portion of the stone from the dark, so as to compare their composition in the principal points. The light-coloured portion was got free from the dark, but the dark remained still mixed with a considerable portion of the light-coloured. The differences observed will be pointed out after the results of the general analysis have been given.

A little phosphorus was found, and is supposed to exist in combination with iron, 1 equiv. to 3 equivs. iron,—Schreibersite.

The results of analysis are as follows:—

Dried at 212° F.

Iron	16.98	91.54
Nickel	1.26	6.79
Cobalt	0.21	1.15
Chromium	0.10	0.52

Nickel iron 18.55 100.00

Iron	2.69	51.54
Sulphur	1.76	33.71
Iron	0.65	12.46
Phosphorus	0.12	2.29

Troilite and Schreibersite 5.22 100.00

Magnesia	13.76	39.11
Lime	0.68	1.93
Soda	0.09	0.26
Protoxide of iron	7.51	21.35
Alumina	0.41	1.17
Silica	10.73	30.50
Loss (removed by carbonate of soda with the silica)	2.00	5.68

Earthy matter soluble in acids 35.18 100.00

Magnesia	10.04	23.70
Lime	1.69	4.00
Soda (with trace of potash)	0.78	1.84
Protoxide of iron	3.65	8.62
Oxide of chromium	0.40	0.95
Alumina	1.36	3.22
Silica	24.44	57.67

Earthy matter insoluble in acids 42.36 100.00

101.31

The earthy matter insoluble in acid is augitic in character, and closely resembles, in composition, the minerals tremolyte and actynolyte, except that above two-thirds of the lime in those minerals is replaced in this by protoxide of iron. It also contains chrome-iron to the extent of 1.39 per cent, or 0.59 per cent of the entire stone.

The earthy matter soluble in acids is somewhat similar in composition to chrysolite or peridotite, but contains a larger proportion of magnesia and iron. There is probably a much greater mixture of different minerals than in the case of the insoluble portion.

There is a little chromium soluble in acid, and also soluble in iodine, at least partially. I have supposed it to be a constituent of the nickel iron alloy.

Several portions which had been treated with acids (in which, consequently, uncombined iron could not be estimated) contained, in the soluble portion, more silica than is given in the above analysis (about 2 per cent more). The proportion of matter insoluble in acid, in these cases, was about 39.5 per cent of the whole stone.

Attention was directed, as already stated, to the differently-coloured portions of the stone. Analysis gave the following results:—

	Light-coloured.	Dark-coloured chiefly.
Specific gravity in small pieces	3.743 ..	3.612
„ again wetted ..	3.763 ..	3.704
„ in powder ..	3.818 ..	3.729

Constituents Soluble in Acids.

	Light-coloured.	Dark-coloured chiefly.
Uncombined iron	17.77 ..	16.20
Sulphur	1.75 ..	1.77
Magnesia	13.65 ..	13.88
Protoxide of iron	6.67 ..	7.76
Cobalt	{ all, or	{ none, or
	{ nearly all.	{ nearly none.

The portion insoluble in acids differed little in the two kinds. It will be observed that the principal difference is in the relative proportion of uncombined and oxidised iron, the dark portion containing most oxide of iron, the light part containing most uncombined iron, and all, or almost all, the cobalt. The higher specific gravity of the light-coloured portion accords with the greater quantity of metallic iron it contains. The state of oxidation of the iron was not experimentally determined, but was assumed to be that of protoxide, in accordance with the analyses given of similar terrestrial minerals. The cause of difference between the loss of weight sustained by boiling the mineral after the action of acids and the weight of the silica obtained appears to depend upon small quantities of other constituents, removed by the carbonate of soda in solution or in very fine states of suspension. In one experiment, made with great care, the difference of weight was nearly accounted for in this way in alumina and oxide of iron, lime, and magnesia. In this case, the loss of weight by carbonate of soda was 12.015 grs.; the silica obtained 11.563 grs., loss only 0.452 gr. Of the above constituents, there was obtained 0.315 gr., leaving only unaccounted for 0.137 gr. from 100 grs. of the stone.

I have compared its composition with that of other stones, as given in Buchner's "Treatise on Meteorites," Leipzig, 1863, and find it bears a pretty close resemblance to that of "Blansko," (Brünner Kreis, Mähren), November, 1833, and that of "Insel Oesel," in Russia, April, 1855, and a still closer one to that of "Klein-wenden," by Nordhausen, Prussia, of September, 1843.

ON TWO PECULIAR PRODUCTS IN THE NICKEL MANUFACTURE.

By JOSEPH WHARTON.

I.

SEVEN years ago, when I was about to commence operations at Gap Nickel mine and furnace, I noticed among the fragments left by my predecessors a piece of nickel matt which contained occasional plates apparently of a metallic substance, tough, pliable, and elastic; these plates were about as thick as fine writing paper, from $\frac{1}{8}$ inch to $\frac{1}{4}$ inch wide, and about twice as long. No chemical examination of them was made except a slight qualitative examination showing the presence of nickel, iron, and copper.

Having on several occasions subsequently noticed some tendency to a similar appearance in the matt, I gave directions that, when it should next be observed, a close examination should be made, after the extinction of the furnace producing the peculiar matt, of the solid mass which always remains in the bottom of the furnace.*

This solid mass consists in part of lumps of ore, flux, and fuel of the first charge, which reached the hearth imperfectly melted or consumed and so remained, and in part of accretions from the thoroughly fused matt which, as the furnace worked, formed a pool over and enclosing those lumps.

The cavities of such a mass seemed to me favourable for the production of crystals when a tendency to crystallise existed.

Last midsummer very interesting groups of crystals were, in fact, found upon breaking up one of these masses to fit it for re-melting; they were so small, however, that, except for search being made in consequence of the matt of that furnace having exhibited the plates above named, the crystals would probably not have attracted attention.

* It should be explained that the furnaces in question are small upright blast furnaces, in which the ores of Gap Mine (Nickeliferous Pyrrhotite with 2 per cent Ni and Co), previously roasted, are melted for the first time, the product being a matt containing about 12 per cent Ni and Co, with about 4 per cent Cu.

Some of these crystals are cubical, with a bright metallic lustre, the groups closely resembling miniature geodes of galena; others are minute octahedrons, arranged in spicula, and in dendritic or plumy forms, resembling the fern-like aggregations of zinc crystals which I sometimes found in the prolongs of my spelter furnaces at Bethlehem, Pa.

These crystals are very tough, and are highly magnetic. A spicula of the octahedrons can be bent many times without breaking, and one which was floated upon water, after being lifted a few times by a magnet, pointed steadfastly to the north, and showed attraction and repulsion to the poles of a magnet just as a steel magnetic needle would under like circumstances.

A specimen of the octahedral crystals, and a specimen of the granular or almost crystalline solid matter to which they were attached, were submitted for analysis to the chemist of my establishment with the following results:—

	Crystals.		Granular.	
Cu	1.85	0.466	1.74	0.438
Ni and Co ..	25.22	6.837	28.20	7.640
Fe	64.10	36.622	62.50	35.861
S	8.90	43.925	7.60	43.939
	100.07	1:4.93	100.04	1:5.78

The subordinate column in each case shows the quantity of S which would be requisite to form, with the metals found, the compounds Cu_2S , Ni_2S and Co_2S , FeS ; the ratio, below it, is that of the S found to that thus calculated.

If we conceive the copper to exist as Cu_2S , we then have 89.32 parts Fe, Ni, and Co in combination with 8.43 parts S: taking then the average atomic weight of the metals according to the proportions found, as 56.85, the atomic ratio of the metals to that of the sulphur is as 31.4 to 5.27, corresponding very closely to the formula R_6S .

Should the copper be included in the average, we get the figures R 32.00, S 5.56, indicating, though less accurately, the same formula.

II.

Desiring last year to make, in a granulated form, an alloy consisting of $\frac{1}{2}$ nickel, $\frac{1}{2}$ copper, I caused a mixture of the oxides of those metals in the due proportions to be heated in closed crucibles with charcoal in a blast furnace; by this means reduction and fusion resulted, and the fused alloy was poured into water at a high white heat.

Among the granulated metal were found large numbers of hollow spheroids varying in size from peas to large chestnuts, many of them imperfect and torn, but many of them tolerably regular in shape, one side being usually bright and smooth, while the other was rough and pimpled.

As, upon crushing these with a hammer, the anvil was moistened, I examined a considerable number of them, and found that they were nearly full of water, so that the water distinctly rattled within them when shaken, and showed itself in quantity when the larger spheroids were carefully broken. Fluid metal, poured white-hot into water, had formed metallic bulbs filled with water.

For several days I carried some of these bulbs in my pocket, occasionally rattling the water in them, before the manner of their formation occurred to me. My first idea—that drops of metal falling upon the water were flattened by the blow, and that the edges then instantly clasped together and became welded, enclosing water within their grasp—was obviously untenable, for the eye could detect no seam or crevice, and besides, how could water exist as a liquid shut in by walls of this refractory alloy at a welding heat? Apple dumplings are formed in a manner somewhat similar to that, but these bulbs were not so formed.

The true solution is doubtless this: The metal when poured was in a state of ebullition, was giving off gas; not probably metallic vapour, but perhaps carbonic oxide.

The separate globules into which the thin stream divided upon entering the water, were each emitting gas when contact with the water produced upon their surfaces an impervious film of solid or pasty metal. The continued evolution of gas in the fluid interior of such globules could have then no other effect than to distend the globule into a bulb, whose upper side might well be pimpled by the effort of tiny gas bubbles in the pasty shell to escape upward, while similar tiny bubbles working upward in the crust of the under side would reach the interior cavity, thus leaving the lower surface smooth and bright.

Multitudes of incipient globules were, of course, torn and distorted by reason of the internal gas finding a vent, and, of course, any which were rent must necessarily be filled by the water in which they were plunged. Those, however, in which the eye found no aperture were doubtless filled, after the coldness of the external water had so contracted the heat-rarefied gas as to produce an approximate vacuum within the bulb, by the slow imbibing of water through minute pores to supply that vacuum. That such pores existed was shown by the fact of the bulbs all, in time, losing their water by exposure to a desiccating atmosphere.

Not all the pots of metal produced, when poured, such globules, for not all were in the fit state of ebullition.

The nature of the disengaged gas might perhaps have been determined, if a sufficient quantity had been collected by breaking the globules under a receiver, but this was not done.—*Am. Journ. Sci.*, xlix., 365.

Philadelphia, March, 1870.

INVESTIGATION OF FLAME-TEMPERATURES, IN THEIR RELATIONS TO COMPOSITION AND LUMINOSITY.*

By Profs. B. SILLIMAN and HENRY WURTZ.

I.

CALORIFIC POWERS OR EFFECT OF GASES.

THESE subjects lie, in our belief, at the very basis of the true theory of the phenomena of luminiferous gases, and have practical bearings that can scarcely be overrated.

In fact, our studies of the subject have led us in the direction of the general conclusion that, all other conditions being equal, the temperature in a given flame is the main factor of luminosity. This, however, may as yet be regarded merely as an hypothesis, in consequence of the imperfection of our present means of actual experimental demonstration of the temperatures of flames. It is an hypothesis, nevertheless, which is in general accordance with known facts. By the spectroscopic, for example, which can recognise only luminous rays, we find that the higher the temperature the greater the number of these luminous rays. The recent results of Frankland upon the development of luminosity by increased pressure, in flames which are non-luminous under atmospheric pressure, are in accordance with this view; increase of temperature necessarily following increase of pressure.

Very vague views have been rife, even among chemists, with regard to the temperatures of luminiferous flames. Some have been satisfied with believing crude hypotheses—such as that the heat-power of a flame is always proportional to the density of the gas or vapour undergoing combustion, or that it is proportional to the amount of oxygen consumed by a given volume of the gas, and so on. This latter hypothesis has been one of very common acceptance. A view which is even now entertained by some

* Read to the American Association at Salem. Communicated by the Authors.

skilful chemists (than which, however, nothing, as will be shown below, could be more fallacious) is that those individual gaseous compounds which impart the highest luminosity, under ordinary conditions, are also the most productive of heat.

The admirable researches of the great gas-chemist, Bunsen, of Heidelberg, placed in our possession, some years ago, the means of computing, at least with approximate accuracy, the heat of flames of gases of known compositions. Few, however, have properly and successfully applied Bunsen's method in practice. We consider it quite time that these methods should be introduced to the knowledge of gas-engineers, in forms available to them.

Bunsen's *formula* for these computations are based upon the actual experimental determinations of the *total* amounts of heat developed by the combustion of different pure combustible gases with pure oxygen made by Favre and Silbermann, and upon Regnault's determinations of the specific heats of gaseous products of combustion.

It is not to be maintained that Favre and Silbermann's numbers are strictly correct, but they are doubtless approximate, and at least proportionately correct among themselves; at any rate, they are the best data we have. Those employed here are included in the following table. They are usually given in the text-books for equal *weights* of the gases; but we have reduced them to the standard of equal *volumes* also, as more suitable to our present purpose. This reduction is made simply by multiplying the equivalents for weights by the densities as given in the third column.

TABLE I.

Total calorific equivalents

	Of equal weights.	Of equal volume.	Densities on scale of hydrogen = 1.
Carbonic oxide	34,462° C. . .	34,462° C. . .	1.0
Hydrogen	2,403° . . .	33,642° . . .	14.0
Marsh gas	13,063° . . .	104,504° . . .	8.0
Olefiant gas	11,858° . . .	166,012° . . .	14.0

The meaning of this table is simply that equal weights of water would be heated by the several gases to temperatures proportional to the numbers in the first column when equal *weights* of the gases are burned, and proportional to those in the second column when equal *volumes* are burned.

A cursory glance at the figures in the second column of this table might seem to justify the notion hitherto entertained by many of the comparatively-low calorific powers of hydrogen and carbonic oxide; and it was doubtless as a consequence of such a comparison as this that statements have been put forth and widely accepted among American gas-engineers to the effect that the weight of water heated from the freezing to the boiling-point by 1 cubic foot of the four main components of illuminating-gas, respectively, is as follows:—

Hydrogen	2.22 lbs. water
Carbonic oxide	2.16 "
Marsh gas	6.17 "
Olefiant gas	10.74 "

The figures here being obviously about in the same ratio as those in the second column of Table I. Several most grave errors, however, are here involved. To get at the true relative calorific effects of the above gases, when burned in the open air, in heating water below its boiling-point, deductions must be made, not only for the *specific heats* of the products of combustion of the gas, but also (more important still) for the specific heat of the *nitrogen of the air* required to burn the gas. In fact, when we consider that, for each volume of oxygen required to burn a given volume of a gas, about *four volumes* of nitrogen must be heated up to the temperature of the

flame, it becomes easy to conceive, what is actually the fact, that, within certain limits, the waste of heat due to this cause alone counterbalances altogether the advantage that would be supposed to result from the crowding of combustible matter into so condensed a form as in the illuminating hydrocarbons. An inevitable result of our investigations of this matter is that the heating powers of the flames of pure hydrogen and pure olefiant gas, even when used to the greatest advantage, to heat water below its boiling-point are almost or quite identical.

In this discussion we have occasion to use the numbers representing the specific heats of but *three* gases—the three, namely, which remain after complete combustion, *steam*, *carbonic acid*, and *nitrogen*; as we must assume that, in the hottest and most luminous zone or shelf of the flame, there is no oxygen in excess to be heated. These three numbers are, according to Regnault's latest determinations, for equal weights of—

Steam	0.4805
Carbonic acid	0.2163
Nitrogen	0.2438
(Liquid water being	1.0000)

This means that the amounts of heat which would raise 1 lb. of water and steam to the *same degree* are in the ratio of 0.4805 for the pound of steam, and 1 for the pound of water.

Calculation of the Calorific Effect of Hydrogen Burning in Air.

Let us take first the simplest case possible, that of hydrogen with exactly the right admixture of pure oxygen to burn it, which, by Table I, develops a total heat of 34462° C., that is, would heat a certain weight of *liquid* water to this temperature. In order to find the actual amount of heat contained in the products of combustion, we must first take into account the fact that 1 lb. of hydrogen burns to *nine pounds* of steam, and then obtain the ratio between the above number, 34462, and the amount of heat necessary to heat nine times the weight of steam, that is, nine times the specific heat of steam. Calling the total residual heat in the produced steam *x*, we have the simple proportion—

$$9 \times (\text{sp. heat of steam} = 0.4805) : 34462 :: (\text{sp. heat of water} = 1) : x;$$

Or—

$$x = \frac{34462^\circ}{4.3245} = 7969^\circ \text{ C.} = 14376^\circ \text{ F.};$$

a number which, we may add, represents the *maximum* of heat capable of being imparted to *liquid water* by the flame of Hare's oxyhydrogen blowpipe.

Still, we have by no means here the actual temperature of the free or open flame of Hare's blowpipe, which is generally *lower* than this figure, as we have not yet taken into account the "latent heat," or heat of vapourisation, of the 9 lbs. of steam formed. The centigrade temperature necessary to convert 1 lb. of water into steam being 537°, to get the *actual temperature* of the oxyhydrogen flame we must modify the above equation, so that—

$$x = \frac{34462^\circ - (9 \times 537^\circ)}{4.3245} = 6851^\circ \text{ C.} = 12364^\circ \text{ F.};$$

which is the temperature actually possible in the flame of the compound blowpipe, *were the combustion instantaneous and complete.*

When hydrogen gas burns in *air*, however, as has been before stated, another deduction of enormous amount must

* Bunsen, in his "Gasometry" (English edition of 1857, p. 242), gives this number as 8061° C., the difference being due to the use by him of a different number for the specific heat of steam, namely, 0.475, apparently an earlier determination of Regnault. Bunsen makes here the singular oversight of regarding this figure as the temperature when "the gases can freely expand, as is the case in an open flame," overlooking the correction necessary in this case for the *latent heat of steam of combustion*, as is explained in the text above.

be made from the above figures, due to the heat required to expand the nitrogen. This is obtained simply by adding to the divisor, as above, the weight of the nitrogen of the air employed, multiplied by its specific heat. The weight of the nitrogen in air = 3.318 times the oxygen; so that the latter of the above equations becomes—

$$x = \frac{34462^\circ - (9 \times 537^\circ)}{4.3245 + (8 \times 3.318 \times 0.2438)} = 2744.5^\circ \text{C.} = 4972^\circ \text{F.}$$

[We have here a full explanation of the extraordinary rate of degradation of illuminating-gas by admixture of air, which we have discussed elsewhere. The nitrogen of such air is not merely a diluent, or even a mere deductive, quantity; its specific heat is an actual *divisory* function in diminishing the flame-temperature.]

This, then, is the actual temperature to which the flame of hydrogen gas burning in the atmosphere might attain to, supposing complete and instantaneous combustion. If it is desired to obtain, instead, the total calorific effectiveness, as in heating water below its boiling-point (in which case the latent heat of the steam of combustion becomes also available), the above expression is changed by simply omitting the subtrahend in the numerator—

$$x = \frac{34462^\circ}{4.3245 + 6.4714} = 3192^\circ \text{C.} = 5778^\circ \text{F.}$$

Calculation of Calorific Effect of Carbonic Oxide Burning in Air.

As the product of combustion is here solely carbonic acid, no latent heat of steam enters, and the calorific effectiveness is the same under all circumstances in air. In the numerator, we substitute, of course, the calorific equivalent of 1 volume of carbonic oxide from Table I; and, in the denominator, for the specific heat of 9 lbs. of water, that of 22 lbs. of carbonic acid, being the weight of the latter formed by the combustion and combination of 14 lbs. (weight of a volume of carbonic oxide on the hydrogen-scale by third column of Table I) of carbonic oxide with 8 lbs. of oxygen. The number for the specific heat of nitrogen is the same as before; and the equation is now—

$$x = \frac{33642^\circ}{(22 \times 0.2163) + 6.47 = 11.23} = 2996^\circ \text{C.} = 5425^\circ \text{F.}$$

Marsh Gas and Olefant Gas.

In these two cases, we have, as products of combustion, both carbonic acid and water; and, therefore, when the calorific effects are sought for, we have not only the latent heat of steam entering as a subtrahend into the numerator, but also into the denominator, as divisors, all three of the specific heats of steam, carbonic acid, and nitrogen.

Then, as 8 lbs. of marsh gas consume 22 lbs. of oxygen, and produce 22 lbs. of carbonic acid and 18 lbs. steam; and, as 14 lbs. of olefant gas consume 48 lbs. of oxygen, producing 44 lbs. of carbonic acid and 18 lbs. of steam: the equations for the calorific powers of their flames in air become:—

For marsh gas—

$$x = \frac{104504^\circ - (18 \times 537^\circ)}{(18 \times 4805) + (22 \times 2163) + (32 \times 3.318 \times 2438)} = 2414^\circ \text{C.} = 4386^\circ \text{F.}$$

And for olefant gas—

$$x = \frac{166012^\circ - (18 \times 537^\circ)}{(18 \times 4805) + (44 \times 2168) + (48 \times 3.318 \times 2438)} = 2743^\circ \text{C.} = 4970^\circ \text{F.}$$

When the deduction for the latent heat of the steam of combustion is not made, the results in these two gases are considerably higher, as will be obvious from mere inspection of the formulæ.

We shall now give, in tabular form, all the results of

our calculations of the calorific powers, when burning in the air, of the four gases we have to deal with.

TABLE II.

For equal volumes of the gases burning in air.	Calorific effects in heating liquid water.		Calorific effects above 100° C.	
	C.	F.	C.	F.
Hydrogen { (Sp. heat, HO = 0.4805)	3192°	5778°	2744°	4971°
{ (Sp. heat, HO = 0.4750)	3204°	5799°	2755°	4991°
{ Mean	3198°	5788°	2749°	4980°
Carbonic oxide	2996°	5425°	2996°	5425°
Marsh gas (sp. heat, HO = 0.4805)	2666°	4820°	2414°	4386°
Olefant gas (sp. heat, HO = 0.4805)	2916°	5481°	2743°	4970°

Computation of Calorific Effects of Mixed Gases.

The above table renders the calculation of the calorific effects of any given gaseous mixture whose centesimal composition is known a matter of extreme simplicity. It is only necessary to obtain the sum of the multiples of the percentage of each component gas into its calorific capacity, as given in the Table, and divided by 100.*

To serve as examples of these modes of computation, we here cite, in tabular forms, the results of some analyses of a number of gaseous mixtures, made by us during the past winter (1868-9). [These analytical results, it may be remarked, possess points of novelty and importance, both scientific and practical, which will bring them up again, hereafter, in other connections. They are here placed on record.]

Table 3 gives the results of two analyses of gaseous mixtures obtained by passing steam, superheated to incandescence, upwards through a mass of anthracite coal heated to a high degree in a clay retort of a novel construction, according to what is now known as the "Gwynne-Harris" or American hydrocarbon-gas system. In this table the results are calculated without carbonic acid and sulphuretted hydrogen, which, with traces of nitrogen, and sometimes of oxygen, are found in the unpurified anthracite gas.

TABLE III.

Analysis of Anthracite Hydrocarbon-Gas.—By Silliman and Wurts.

	I.	2.	Mean.
Hydrogen	60.43	59.32	59.87
Carbonic oxide ..	35.44	37.14	36.29
Marsh gas	4.13	3.54	3.84
	100.00	100.00	100.00

In Table 4, column 1 gives the results of the analysis of the street-gas served out at this period by the New Haven Gas-Light Company, made from Westmoreland coal, enriched with about 6 per cent of Albertite; column 2 the mean of four analyses of the completed hydrocarbon-gas made by us at Fair Haven during the same time, by combining gas from the same Westmoreland coal (with 10 per cent of Albertite) with half its volume of the anthracite gas. Columns 3 and 4 are obtained from 1 and 2 by centesimal reduction, after deduction of the illuminant ingredients, being what we propose to designate as the non-illuminating *substrata* of illuminating-gases.

* Prof. Bunsen, in the masterly discussion of the subject presented in his "Gasometry," not having in view the exact object we propose, has used a train of reasoning and a mode of formulation of some complexity, to follow which requires some little mathematical skill; part of his objects having been to construct a *formula* so general and comprehensive as to cover the direct computation, from any gaseous mixture independently, of its special calorific intensity. We have here aimed at so simplifying as to bring the whole subject within the capacity of all. Our above tabulation of the individual gaseous components, as a starting-point, seems, to us, to accomplish this most effectually, so far as illuminating-gases are concerned.

TABLE IV.

Gas Analyses.—By Silliman and Wurtz.

	New Haven city gas.	Fair Haven hydrocar- bon gas.	Substratum of New Haven gas.	Substratum of Fair Haven gas.
	1.	2.	3.	4.
Hydrogen ..	43.58	46.77	46.79	50.27
Carbonic oxide ..	2.14	9.56	2.31	10.27
Marsh gas ..	47.42	36.71	50.90	39.46
Illuminants ..	6.86	6.96	—	—
	100.00	100.00	100.00	100.00

Table 5 gives the results of the computation, from our formulae, of the calorific powers of these five gaseous mixtures, for communicating temperatures both above and below that of aqueous ebullition. We should remark that we have been obliged to regard the volumes of *illuminant hydrocarbons* as representing olefiant gas solely, both because we have no certain data as to their real nature, and particularly because, if we actually knew or should assume the nature of the hydrocarbon-vapours present, still we have no experimental calorific equivalents, as we have for olefiant gas, from which to start in such a computation. We have reason to believe, nevertheless, that the errors thus introduced are not important in amount.

TABLE V.

	Weights of water equally heated below boiling; by equal volumes.	Weights of water equally heated above boiling; by equal volumes.	First column reduced to New Haven gas = 100.	Second column reduced to New Haven gas = 100.
Anthracite gas ..	3100	2828	104.2	109.2
Substratum of the New Haven street-gas ..	2917	2581	98.1	99.6
Substratum of the Fair Haven hydrocarbon gas ..	2962	2640	99.6	102.0
New Haven gas (with the illu- minants assumed = olefiant)	2974	2592	100.0	100.0
Fair Haven gas (with the illu- minants assumed = olefiant)	2959	2647	99.5	102.1

Conclusions.

Some of the practical conclusions to which we are of necessity compelled by the results of the above investigations are somewhat remarkable; so that we feel diffident regarding them. It is, however, always safe to follow the leading of Truth, however astray she may conduct us from our preconceived notions.

From Table 2, it is apparent:—

1. That, of all known gases, the highest calorific effects, under ordinary atmospheric conditions, are obtainable from *carbonic oxide*, whose calorific value, above 100° C., is about 3000° C.

2. That, in absolute calorific value, below 100° C., in the atmospheric medium, *hydrogen* surpasses its volume of any other gas, giving a temperature of about 3200° C.

3. That for all modes of application—that is, for producing both high and low temperatures—the total maximum calorific effectiveness of carbonic oxide is a *constant quantity*.*

4. Compound condensed submultiple volumes of hydrogen, like that in marsh gas, have much *less* total calorific value in air than their volume of free hydrogen.

5. Condensed compound submultiple volumes of gaseous carbon, like that in olefiant gas, have no greater total calorific value in air, below 100° C., than their own volume of carbon gas in the form of carbonic oxide; while above 100° C. their value is even considerably less.

* Metallurgists, especially, will appreciate the suggestive import of the truths presented under the first and third heads; here enunciated, as we think, for the first time. It is to be noted that all the above effects belong to the *maximum* kind, and, of course, reach their development only under the most favourable conditions in each case respectively.

TANTALUM AND NIOBIUM.*

By Prof. ALBERT R. LEEDS.

IN a long and interesting review of the great investigation of tantalum and niobium which occupied the last twenty years of H. Rose's life, Rammelsberg re-computes the formulæ according to the modern theories of chemistry, and shows that Rose's mistakes were not so much in the analyses as in the formulæ he deduced from them.† Blomstrand and Marignac have already pointed out that Rose fell into the error of regarding as a chloride what they demonstrated to be an oxychloride.

In order to obtain metallic tantalum, Berzelius heated tantalum-potassic fluoride with potassium: on treatment with water, there remained behind a heavy, black powder. H. Rose employed 3 parts tantalum-sodic fluoride and 1 part sodium: here, also, remained a heavy powder, which contained a considerable quantity of sodic bitantalate. Marignac reduced tantalum-potassic fluoride with aluminum: by treatment of the regulus with chlorhydric acid, a grey, crystalline powder remained behind of the composition Ta_2Al_3 . Marignac did not succeed in preparing pure tantalum; and, up to the present time, it is unknown. The impure tantalum obtained by Rose conducted electricity very well; changed, with incandescence, on heating in the air, into tantic acid; and was attacked by no acid except fluorhydric, and by that very slowly. The atomic weight of tantalum, as determined by the decomposition of tantalum-potassic fluoride into tantic acid and potassic sulphate, was 182. Tantic chloride was obtained by heating tantic acid and carbon in an atmosphere of chlorine. It melts, according to Deville, at 241.6° C., and volatilises entirely, forming a crystalline sublimate. According to the same chemist, it fumes in the air, expels HCl, and covers itself with tantic acid. Its formula, as derived by Rose from the amount of chlorine it yielded, is $TaCl_5$. To prepare pure tantic acid, it is recommended to decompose tantalite by fusion with potassic bisulphate, and to fuse the salts which separate out with acid fluoride of potassium. The difficultly-soluble tantalate is allowed to crystallise out of the solution of the double fluorides, and is decomposed by heating with sulphuric acid, &c. It is white; when heated, faintly yellow; and has a formula, Ta_2O_5 . Its numerous salts are arranged, by Rammelsberg, in five series, corresponding to the different stages of saturation of the acid.—*Journal of the Franklin Institute*.

CORRESPONDENCE.

ASSAY OF MANGANESE ORES.

To the Editor of the Chemical News.

SIR,—In his paper on the "Estimation of Peroxide of Manganese in Manganese Ores" (CHEMICAL NEWS, vol. xxi., p. 267), Mr. Pattinson points out a probable source of error in the Fresenius and Will method of testing manganese.

Speaking of hard ores containing magnetic oxide of iron, he says—"In order to affect their decomposition it is necessary to add a large quantity of sulphuric acid and to apply extraneous heat for a considerable time. It is probable that during this lengthened heating steam is allowed to escape with the carbonic acid, and hence a higher amount of peroxide is indicated than is present in the ore."

That this could not have been the cause of the higher results obtained by this method, in the experiments given in the paper on the "Estimation of Peroxide of Manganese

* Communicated by Professor Morton.

† *Journ. für Prakt. Chem.*, 1869, p. 334.

in Manganese Ores" (CHEMICAL NEWS, vol. xx., p. 302), is evident from the fact that in the three tests there given, extraneous heat was in no case applied to the apparatus, and, therefore, the boiling-point was not reached.

I have since tested three different samples of manganese by the Bunsen and by Fresenius and Will's method, which, by the latter, gave results from 1 to 1½ per cent higher than by the former, and in testing them by Fresenius and Will's method I took the precaution of connecting the apparatus with weighed chloride of calcium tubes during the heating and drawing of air through the apparatus, and found after repeated heating to the boiling-point, no increase in the weight of the chloride of calcium tubes, and no decrease in the weight of the apparatus. The higher results obtained in these cases by the Fresenius and Will's method cannot, therefore, be due to the escape of steam.

I have tried the method described by Mr. Pattinson, and obtained results agreeing very closely with each other.—I am, &c.,

EDWARD SHERER.

June 11th, 1870.

THE ENGLISH COMMERCIAL SODA-TEST.

To the Editor of the Chemical News.

SIR,—My attention has lately been drawn to a strange error made by some analysts in attempting to apply the English commercial test for soda to samples of alkali, soda-ash, &c., the result of which error is to make the test indicate from 1 to 1½ per cent more soda than the sample contains by the proper English test. It is well known that this (the English soda-test) had its origin in the early days of the soda trade—when chemists believed the equivalent of soda to be 32, and that of carbonate of soda 54; and that, consequently, test acid was made so that 40 parts of sulphuric acid neutralised 54 parts of carbonate of soda equal to 32 of soda. This method of testing has always been, and still is, used by the soda trade throughout England; and it is a custom well understood by both buyers and sellers. It indicates 0·66 per cent more soda in a 50 per cent alkali, than the rigidly-correct test based on the new equivalent 31 would indicate. It is certainly desirable, for the sake of scientific accuracy, that the correct equivalent, 31, should be used in testing; but, seeing that manufacturers have expended their capital in plant, and made their contracts for their various materials on the understanding that a product containing a certain percentage of soda would be obtained, and, seeing that there are other commercial customs of the trade still in force, which tell as much against the manufacturer as the test does in his favour—such, for instance, as that of not charging for fractions of percentages, it is more the province of an association like the Alkali Manufacturers' Association, than that of an analytical chemist, to make alterations in trade usages affecting such vast interests. Certainly, if any alteration be made at all by chemists, it should be made in the direction of scientific accuracy, and not in the contrary direction, as in the case to which I have referred. The error, I find, arises in this way: The test-acid is made so as to indicate the exact amount of soda according to the new and correct equivalent 31—that is, that 40 parts of sulphuric acid should neutralise 53 parts of carbonate of soda, equal to 31 parts of soda.

To convert the results obtained by this test-acid into the English commercial soda-test, it is incorrectly assumed that the 31 parts of soda are equal to 32,—in other words, that the 53 parts of carbonate of soda contain 32 parts of soda. This is where the error lies; for, according to the correct English test, 54 parts of carbonate of soda, and not 53, contain 32 of soda; and, therefore, by the English test, 53 parts of carbonate of soda contain only 31·41 of soda. By thus mixing up the old and the new systems of equivalents, a sample of soda-ash which, by the correct English test, contains 50·66 per cent would be returned

as containing 51·61 per cent of soda. A sample of caustic soda which, by the correct English test, would contain 75·0 per cent of soda would, by this erroneous method, indicate 76·4 per cent. It is only necessary to point out this error in order that it may be avoided and guarded against by any of your readers interested in the buying and selling of alkalies.—I am, &c.,

JOHN PATTINSON.

Newcastle-upon-Tyne,
June 7th, 1870.

MISCELLANEOUS.

Double Sulphide of Potassium and Iron.*—By heating an intimate mixture of 5 parts of sulphur, 5 of potassic carbonate and 1 part of fine iron-filings, C. Preiss has succeeded in forming a double sulphide of potassium and iron, which crystallises in red needles, has a metallic lustre, and resembles in appearance potassic permanganate. Its formula is $\text{KS,Fe}_2\text{S}_3$.† The same compound has been obtained independently by R. Schneider, who also has formed, by the replacement of iron by bismuth, the analogous compound, $\text{KS,Bi}_2\text{S}_3$.—*Pogg. Ann.*

Application of Mica as a Substitute for Bronze.*—A means has been found of greatly increasing the value of mica, by converting it into a colouring material. The mica is reduced to small pieces in a stamping mill, digested with chlorhydric acid, cleansed by washing and sorted by sieves into sizes. The mica scales so prepared have a beautiful vitreous lustre, a silvery appearance, and bear in commerce the name of Brocade Crystal Colours or Mica Bronzes. The advantages of these brocades over the common metallic ones are:—(1). They contain no unwholesome substance. (2). They possess a metallic lustre like the metallic brocades, and much surpass them in splendour. (3). Brown, blue, black, green, and red colours of rare brilliancy can be obtained, which is not the case with the metallic brocades. (4). They are not dimmed by sulphur vapours. The analyses by Dr. Cech and Schneider show that the colouring matter of the rose-brocade is cochineal; that of carmine is fuchsine; bright red, fuchsine and Havanna brown; violet, Hofmann's violet; bright blue, Berlin blue; dark blue, probably impure aniline blue or Girard's violet; light and dark green, a mixture of aniline blue and curcuma; gold, curcuma; silver, the mica alone, &c.—*Journ. für Prakt. Chemie.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, June 6, 1870.

This number contains the following original papers and memoirs relating to physico-chemical and collateral sciences:—

Action of Water upon Iron, and of Hydrogen upon the Oxide of Iron.—H. Sainte-Claire Deville.—(Second paper on this subject.) The author describes at length the phenomena observed when iron is heated to 150°, 265°, 440°, 860°, 1040°, and, lastly, to the highest temperature porcelain can bear without becoming soft—first, leaving the tension of the vapour constant; and, secondly, varying it. Curiously enough, the author finds that, the higher the temperature iron is heated

* Communicated by Professor Morton.

† *Journ. für Prakt. Chemie*, cviii., p. 10.

to, the less it decomposes water; in chemical parlance, the author says, we should say that the affinity of iron for the oxygen of water decreases with the increase of temperature. The lengthy memoir contains a series of tabulated results of experiments; and the author winds up with a metaphysical discussion on the real signification of force.

Reduction of Nitrous Acid by Metals.—E. Fremy.—The author, referring to his former paper on this subject, now states that the oxy-ammonia discovered by M. Lossen, and also obtained by the author as the result of the decomposition of nitrous acid, was now prepared on purpose, by causing a mixture of chlorhydric acid and tin to act upon the nitric ether of wood-spirit; and, on studying its properties, he finds these to agree with what has already been said. The author then describes the action of sodium-amalgam upon a nitrate, which is thereby first converted into a nitrite, and this, in its turn, into oxy-ammonia, nitrogen, [and protoxide of nitrogen, which gas, however, remains in solution in the alkaline liquid.

Optical Properties of Benzyl, and of some Substances belonging to the Camphor Groups, in the Crystalline State and in Solution.—M. Des Cloizeaux.—In this lengthy memoir, the author describes a series of experiments, the chief results of which are that benzyl and periodate of soda possess, when in solid crystalline state, strongly-marked rotatory powers, and are devoid thereof in the state of solution. Quartz, chlorate, and bromate of soda act the same. Sulphate of strychnia possesses rotatory powers, in crystalline as well as in dissolved state; while ordinary camphor, patchouli camphor, camphor (stearopten) of oil of mint, Borneo camphor, terecamphen, and monochlorhydrate of turpentine, possess rotatory power when in solution, but not in crystalline state.

Displacement of the Rays observed in the Solar Spectrum.—A letter to M. Fizeau on this subject from the Rev. Father A. Secchi, S.J.

Rectification of some Dates relating to the Rev. M. Grandillon's Life.—A. Georget.—The author states that the Rev. M. Grandillon was Professor of Natural Philosophy at Orleans in 1677; from 1619–1623, he was successively Professor of Logic, Metaphysics, and Divinity at La Flèche; in 1624 and 1625, Professor of Divinity at Paris; 1626 and 1627, Prefectus Studiorum and Concionator at Bourges; from 1628–1630, Rector at Alençon, where he died on the 29th of October, 1631. He was a Roman Catholic priest, and a member of the Order of Jesuits before 1614, and was, about that year, Reader on Philosophy at Paris. From a foot-note added to this notice, we learn that the dates alluded to are the authentic figures extracted from the official documents in the possession of the Society of Jesus.

Insalubrity of the Water of the River Croult, and on the means of Preventing its Pollution by the Refuse from Starch Manufactories.—M. Gérardin.—Only the title is given of this paper.

Formation of Blood Globules.—Dr. Felz.—The author states that, from some observations made by him, these globules are formed also outside of the blood vessels, but are not then coloured. He quotes, as instances, the presence of white blood globules in the tissue of the cornea of the eye, cartilage, and similar tissues.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 8, 1870.

This number contains the following original papers and memoirs:—

Action of Chlorine upon Aldehyde: a New Chloral.—G. Krämer and A. Pinner.—The authors relate, at great length, a series of experiments made by them with some peculiar by-products obtained in the industrial manufacture of aldehyde, as now carried on in Germany. These products appeared to be perfectly useless, even for burning in spirit-lamps; and, hence, the authors investigated the possibility of applying that substance to the preparation of chloral (hydrate of). In the course of these researches, they obtained what they call a new chloral—after purification, a colourless oily fluid—which absorbs water with great avidity; but, when a single drop of that fluid is added to some of the oily liquid, it does not mix therewith. On being, however, stirred together, heat is evolved, and the mixture solidifies, forming a solid crystalline mass. The body also combines with alcohol; its percentage composition is—Carbon, 27.56; hydrogen, 3.07; chlorine, 69.4; vapour density, 86.01. These figures, the authors say, suit croton-chloral as well as butyl-chloral—the former being $C_8H_7Cl_3O$, carbon, 27.66; hydrogen, 1.71; chlorine, 61.38—the latter, $C_4H_7Cl_3O$. The further researches on this subject have proved the new body to be the croton-chloral. A chloride of this substance was obtained, and an acid, which undoubtedly proved that a new chloral had been discovered.

Quantitative Estimation of Glacial Acetic Acid.—F. Rüdorff.—The author preliminarily refers to the usual methods of the estimation in question, by means of a titrated soda solution, stating it to be unsatisfactory; and next mentions that his method is based upon the estimation of the freezing-point of the acid in question. The author enters at length into the details of his experiments, the chief point of interest of which is that perfectly pure and anhydrous acetic acid solidifies at 16.7° ; that if either water, alcohol, some salts, or sulphuric acid are present, these substances tend to lower the point of solidification, so that 100 parts of the pure acid, mixed with 24 of water, solidifies at -7.4° .

Action of Bromine upon Dichlorhydrine.—L. Carius.—After referring to some former experiments on this subject, the author describes dichlor-dibromacetone, $C_2H_2Cl_2Br_2O$, a heavy liquid, not

freezing at -10° , and not boiling without decomposition. When combined with water, this substance forms a solid body, $C_2H_2Cl_2Br_2O + (OH)_2$, containing 20.17 per cent of water of crystallisation.

Toluylen Oxide.—H. Limpricht.—The author describes at length, and with the use of a lengthy series of complicated formulæ, the constitution of—Toluylen oxide—

bromated toluylen oxide—

double bromated toluylen oxide—

The bromated body is a solid, fusing at 50° , crystalline, and giving off bromine at 160° when heated along with water, or at 150° when heated along with alcoholic potassa solution. The dibromated compound is also a solid, crystallising in prismatic-shaped crystals, and fusing at 110° . The author refers to, and to some extent corrects, the statements made by Dr. Zinin in reference to the constitution of these compounds and their connection with other chemical compounds.

Preparation of Hydrated Hydrobromic Acid.—H. Topsøe.—After referring, at some length, to the various modifications made by several authors, among which Drs. Gladstone, Kekulé, Méne, and others, in the preparation of the acid referred to, the author states that, according to his researches, the following mixture suits the purpose best:—Amorphous phosphorus, 1 part; bromine, 10 parts; water, 15 parts (of the latter fluid, a portion is to be placed in the receiver). On distilling this mixture, a colourless fluid is obtained, which becomes gradually stronger (containing more anhydrous acid) until the boiling-point reaches 125° . The acid obtained at that temperature has a sp. gr. of 1.49, and contains 48.17 per cent of anhydrous hydrobromic acid.

Tabulated Forms Exhibiting the Specific Gravity and Percentage Composition of Hydriodic and Hydrobromic Acids at Various Temperatures.—H. Topsøe.—The strongest hydrated hydriodic acid which can be obtained boils at 127° , contains 57.75 per cent of anhydrous hydriodic acid, and its equivalent is 221.7. The equivalent of the strongest hydrated hydrobromic acid just alluded to is 168.2.

Chemical Constitution of Acroleine.—A. Claus.

Source of Error occasioned by the Use of Pettenkofer's Respiration Apparatus.—W. Henneberg.

Contribution to our Knowledge of the Synthesis of Cinnamic Acid.—H. Schiff.—With this, as with many other papers, the great length and large space taken up by a series of very complex formulæ, render any useful abstraction of them impossible.

On Benzoic Acid.—A. Jena.—The author refers, first, to his former researches on this subject, and then states that he has prepared the baryta-salt of this acid, $(C_6H_5O_2)_2Ba$, a crystalline solid substance, readily soluble in water, decomposed, by distillation, into carbonic acid and benzhydrol—

Diphenyl-glycolic acid. Benzhydrol.

The author says that the formula to be assigned to benzoic acid is that which considers it to be diphenyl-glycolic acid.

As a curiosity, we may mention that, from the correspondence of this Society's agents, the gentleman holding that position at St. Petersburg mentions the labours of Lady Anna Wolkow—

On Isomeric Toluiol-Sulpho Acids.—The authoress, having very successfully completed and augmented, by interesting discoveries, the labours on this subject of Drs. Engelhardt and Latschinow. The lady is a member of the Imperial Russian Chemical Society.

Annalen der Physik und Chemie, von Poggendorff, No. 4, 1870.

This number contains the following original papers and memoirs:—

Rotation Phenomenon of Holtz's Machine.—J. C. Poggendorff.

Composition and Constitution of Tourmaline.—Dr. C. Rammeisberg.—The last instalment of this lengthy chemico-mineralogical essay.

Emission, Absorption, and Reflection of the Heat Radiated at Low Temperatures.—G. Magnus.—The last instalment of this lengthy memoir is divided into the following sections:—On reflection of heat; description of experiments; reflection from the surface of other substances than silver, glass, rock-salt, and sylvine; reflection under various angles; results.

Theory of Colours.—Dr. J. J. Müller.—Concluding portion of the memoir on this subject, divided into the following chapters:—On the fluorescence of the retina, as dependent upon the length of waves and the intensity of the light; on the table of colours; physiology of the theory of colours.

Free Rotation of the Movable Conductor and of the Solenoids of Ampère's Apparatus.—Dr. G. Krebs.—Illustrated with engravings.

Tension of Thin Fluid-Plates.—R. Lüdige.

Influence of the Temperature on the Sensitiveness and Delicacy of Spectrum Reactions.—E. Cappel.—The main result which can be drawn from this lengthy paper is, that the temperature most suitable for the spectrum analysis of the alkalis is that of the oxyhydrogen flame; and, for the rest of the metals, the heat of the electric spark is most suitable. The higher the temperature, the more distinct the reactions.

Knochenhauer's Comparison of the Theory and Practice for the Oscillatory Electric Discharges in a Curved and Ramified Closed Conducting Wire.—W. Feddersen.

Floating of Solid Iron upon the Molten Metal, and Observations on the Trèves Experiment.—Dr. L. Overzier.

New Sulphur Salts.—R. Schneider.—(Fourth paper.) Among the large number of salts of this kind discovered by the author, we mention briefly—Cuproplatin-sulphoplatinate—

equivalent, 911.2; in percentages—Copper, 13.93; platinum, 64.99; sulphur, 21.08. Plumbo-platin-sulphoplatinate—

equivalent, 1199.2; in percentages—Lead, 34.58; platinum, 49.35; sulphur, 16.07. Mercurio-platin-sulphoplatinate *cum* mercurio-chloride—

in percentages—Platinum, 34.34; mercury, 46.32; chlorine, 8.22; sulphur, 11.12.

Acoustic Attraction and Repulsion.—K. H. Schelbach.

Flexive Power Exerted by the Contraction of the Muscles.—Dr. R. Most.—An algebraico-physiological paper.

Memoir of the Life of the Late Professor Magnus.—Dr. Pogendorff.

Journal für Praktische Chemie (double number), Nos. 6 and 7, 1870

This number contains the following original papers and memoirs:—

Persulphocyanic Acid and Pseudo-Sulphocyanogen.—Dr. L. Glutz.—Continuation and end of this memoir.

Action of Anhydrous Sulphuric Acid on some of the Chlorine and Sulphur Compounds.—Dr. H. E. Armstrong.—This lengthy memoir is divided into the following sections:—Action of sulphuric anhydride upon tetrachloride of carbon; action of sulphuric anhydride upon chlorobenzol, benzo-trichloride, and dichlorhydrine; action of sulphuric anhydride upon hexachlorbenzol; action of sulphuric anhydride upon sesquichloride of carbon; action of sulphuric anhydride upon sulphide of carbon; action of sulphuric anhydride upon protochloride of phosphorus; properties and reactions of pyro-sulpho-chloride.

Causes and Nature of Chemical Combinations.—Dr. Mohr.

Direct Preparation of Urea from Carbonic Acid and Ammonia.—A. Basaroff.

Some of the Derivatives of Cyanamide.—H. Kolbe.—This lengthy paper is divided into the following sections:—Dicyandiamide and dicyandiamine; cyanurea; dicyanic acid; amidocyanic acid; glyciocaine and kreatinine.

Hydrogenium-Amalgam.—O. Loew.—Hydrogenium-amalgam is prepared by shaking together, in a vessel to be kept very cool, a mixture of mercury containing from 1 to 2 per cent of metallic zinc, along with an equal bulk of a solution of chloride of platinum containing 10 per cent of solid chloride. A slimy mass is obtained, devoid of metallic lustre and prone to decomposition, owing to the presence of some zinc and some compounds of that metal; but, on treating the mass with dilute hydrochloric acid, a body having the consistence of butter is obtained, which, according to the author, is a true amalgam of mercury and hydrogenium. The author describes at length several reactions of this body, which, in many of its properties, is akin to hydrogenium-palladium.

Bulletin Mensuel de la Société Chimique de Paris, May, 1870.

This number contains the following original papers and memoirs:—

Trichlorhydrine and Substances Isomeric with it.—M. Berthelot.—The author says—Trichlorhydrine, a body consisting of carbon, hydrogen, and chlorine, is prepared from glycerine and hydrochloric acid—

But this composition and formula also belong to a series of other bodies, among which those obtained by the following reactions:—The action of chlorine upon the chloride of propylene; action of chlorine upon the chlorinated propylene derived from acetone; action of chlorine upon allyl-iodohydrate ether, isopropyl-iodohydrate ether, and hyduret of propylene; action of perchloride of phosphorus upon acroleine, &c. The author describes at length the comparative investigations made by him on this subject, and summarises the results by stating that tri-

chlorhydrine has not been hitherto produced but from substances which take their origin from glycerine, while there exist at least five series of isomeric chlorinated substances—viz., the derivatives of the hyduret of propylene, C_3H_4 ; the derivatives of the chlorhydrate of propylene, $\text{C}_3\text{H}_5\text{HCl}$; the derivatives of the normal chloride of propylene, $\text{C}_3\text{H}_7\text{Cl}$; the derivatives of the isochloride of propylene; the derivatives of trichlorhydrine corresponding to the glycerine.

On Tribromhydrine.—M. Berthelot.—This paper is a refutation of what has been published by M. Henry on this subject.

Reaction between Oxychloride of Carbon and Benzene.—M. Berthelot.—The result of the author's researches, undertaken with the view to test the accuracy of the results of some investigations made on this subject by Dr. Graebe, is to the effect that free oxychloride of carbon does not, at any temperature whatever, when acting upon benzene, form benzoic chloride.

Substances Isomeric with Trichlorhydrine.—M. Berthelot.—This lengthy essay contains the theoretical discussion on this subject. As might be expected, the paper abounds with formulæ.

Glycol and Oxylic Chlorhydrine.—P. de Clermont.—This paper is divided into the following sections:—Action of nitric acid upon oxylic glycol; chlorhydrine of oxylic glycol.

General Theory of Chemical Action: Action of Chloral upon Aniline.—E. J. Maumené.—The author desires to prove (and this is demonstrated with a series of formulæ) that it may be possible to obtain indigo artificially, by the action of chloral upon aniline; but the practical experiments of the author, as related, do not at all lead to this result.

Les Mondes, May 26, 1870.

Chemically-Prepared Bread.—Dr. Sacc.—The author, writing to the editor, and sending, also, a sample of the bread prepared, says—We are acquainted with bread prepared with substances capable of evolving carbonic acid to render the bread spongy; but, since in bread so prepared the gluten and starch are not, as is the case in bread fermented with yeast, rendered partly soluble, such bread is heavy, and, instead of swelling up, if put into soup it crumbles away and disintegrates. I have tried to remedy this defect, well knowing that chemistry gives us the means and suitable materials to effect the same change as yeast does; and I make use of cheap, simple, and healthy substances, obtainable everywhere (but not further specified). The editor of *Les Mondes* states that the sample of the bread sent him, although it had become dry and stale, was excellent in every respect, but, perhaps, a little too salt for those accustomed to the bread of Paris.

Preparation of Optically-Neutral Sugar.—E. J. Maumené.—The author mixes equal parts of pure sugar candy and neutral nitrate of silver, both previously dissolved in water, and evaporates the mixture upon a water-bath. He states that, neither at 100°, nor even at 140°, any decomposition ensues, or any reduction of silver takes place, provided the sugar be free from inverted sugar. The author confirms, what was found twenty years ago by Dr. G. Mulder, that sugar candy (white) and best refined lump sugar, do not contain any trace of glucose. The sugar rendered syrupy by the process described is optically neutral. The silver-salt is separated from the sugar by means of pure chloride of calcium, and the nitrate of lime is separated from the sugar by the addition of alcohol, and placing this mixture under a bell-jar along with quick-lime. In this manner, by slow concentration, two layers, of different specific gravity, are formed; the upper being an alcoholic solution of nitrate of lime, the lower a viscous saccharine liquid. The former is poured off, and, by a slight washing with cold distilled water, the thick sugar solution is freed from any adhering nitrate of lime. The sugar obtained does not crystallise, does not act upon the cupro-potassic liquor, and readily combines with lime, which base is completely withdrawn by the action of carbonic acid.

June 2, 1870.

Success of a Missionary who Loves Science.—Rev. F. Moigno.—Under this title, the author relates some curiosities of the success obtained by the Rev. A. David, who, as a missionary of the Lazarist Society, has explored Central Asia (Tibet, Mongolia, China), and has brought to Europe a large number of specimens of plants and animals hitherto unknown to Western civilisation. We particularly call attention to this paper, because it contains some very curious statements about a deer-park existing near Pekin, surrounded by a high wall, no less than about 32 miles in circumference, and containing various species of large mammalia not hitherto seen elsewhere. It is rather strange that, since Pekin is the abode of several European Embassies (a French one to boot), the existence of this place *à quelques pas* of Pekin should not have been long since known.

New Manure (Courrière Guano).—MM. A. Tilloy-Delaune and Co.—It appears that Indian corn (*zea mais*) has been, and is now largely used in French distilleries. This grain, previously coarsely broken, is boiled with dilute sulphuric acid, in order to convert its starch into sugar. After fermentation, however, the residue of the distillation is not suitable for feeding cattle. The firm alluded to, large distillers at Courrières (Pas de Calais), run the refuse from the stills into large tanks, and, after all solid matters have subsided, run off the clear liquid, and obtain a residue containing the following percentages:—Water, 8.77; organic matters (inclusive 4.68 nitrogen), 68.35; mineral matters, 18.58; yielding an excellent manure.

Meteorites Observed from November 14th, 1869, to March 11th, 1870.—Rev. Father P. Denza, S.J.—Astronomically-observed meteorites at Moncalieri (Italy).

Improved Centrifugal Pump.—M. Coudurier.—This memoir, illustrated with several excellent woodcuts, states that the pumps alluded to are superior in effect, and surpass in simplicity of construction and force of action any hitherto made. Particulars may be obtained by addressing M. Coignard, 68, Boulevard du Prince Eugène, Paris.

Fermentation and Small Organisms.—E. Du Mesnil.—This rather lengthy paper contains some very curious opinions on fermentation, which is, according to the author's ideas, the joint-work of electricity, magnetism, and ammonia, acting together in a very complex and not well defined manner.

Revue Hebdomadaire de Chimie, May 26, 1870.

Ice-Making Machine and Cooling Apparatus for Brewer's Wort.—L. Martin and M. Vindhaussen.—Lengthy and full description of two apparatus based upon the principle that, if the expansion of a gas (atmospheric air, in this instance) is effected by mechanical means, absorption of heat—in other words, production of cold—takes place. The ice-making machine produces 100 kilos. of ice at a cost of about sixpence. The cooling apparatus is so arranged as to effect a drying of the malt and cool the wort at the same time.

Ammonia Machine.—M. Frot.—The first portion of a paper describing a contrivance wherein ammonia is employed instead of steam for the same purposes for which the latter is now applied.

Chemists' and Mineralogists' Travelling Companion.—MM. Alvergnot.—This paper, accompanied by a woodcut, gives the detailed description of a very neatly-arranged box, 50 by 30 and 20 centimetres, weighing, when full, only 3 kilos., and containing all the necessary requisites for chemical or mineralogical research on a journey and at a distance from laboratories. The makers are celebrated for their goods; the price (not specified) is said to be very moderate.

Tanning by the Aid of Carbonic Acid.—M. Polefroy.—This process consists in submitting the hides (previously limed) to the action of a strong current of carbonic acid, in order to dissolve the tannate of lime first formed, and to aid the penetration of the tannic acid in the skins and hides.

So-called Cold Galvanisation of Iron and Cast-Iron.—V. Rogue.—The iron is first cleaned by being placed in a bath made up of—Water, 1000 litres; chlorhydric acid, 550 litres; sulphuric acid, 50 litres; glycerine, 20 litres. On being removed from this bath, the metal is placed in a bath containing 10 per cent of carbonate of potassa, and is next transferred to a metallising bath consisting of—Water, 1000 litres; chloride of tin, 5 kilos.; chloride of zinc, 4 kilos.; bitartrate of potassa, 8 kilos.; acid sulphate of alumina, 4 kilos.; chloride of aluminium, 10 kilos. The metal has to be left in this mixture for from three to twelve hours, according to the thickness of the layer of zinc to be desired.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, March, 1870.

This number contains the following original papers and memoirs relating to chemistry:—

Substituted Melamines.—Dr. A. W. Hofmann.

Bodies Isomeric with Cyanuric Acid Ether.—Drs. A. W. Hofmann and O. Olshausen.—Both these memoirs are too lengthy for any useful abstraction.

Distribution of the Temperature of Central Europe during the past Winter.—Dr. Dove.—From the various meteorological phenomena observed, the author draws the conclusion that any abnormally-low temperature in Europe travels from the east to the west, while any subsequent abnormally-high temperature moves from the west to the east. The observations quoted in this paper extend over almost the whole of Europe and a large portion of the United States of America.

Revue des Cours Scientifiques de la France et de l'Etranger, May 28, 1870.

Although this number does not contain any paper relating directly to chemistry, we must not omit to quote—

Condition of Sciences during the Middle Ages.—Dr. H. Kopp.—This lecture of the well-known author of the excellent "Geschichte der Chemie" is a very valuable contribution to our knowledge of the history of sciences, as well as to the organisation of the more ancient universities of Europe. We regret that the length of the discourse prevents us entering into details, many of which are interesting as well as amusing.

June 4, 1870.

This number contains the first of a series of lectures on the—

Isomerism of the Elementary Bodies; Different States of Existence of Oxygen.—Dr. Berthelot.—We regret that the length of this paper (a verbatim report) forbids our entering into any detailed abstraction as regards ozone. The author says that there exists, at least in some cases, a certain relation between the states (allotropism of Berzelius) of an element in free state, and the nature of the combination from which it is disengaged; that an elementary body in a certain state can more readily enter into one kind of combination than in another: that an elementary body can change (can

become allotropic) simultaneously whilst it is in combination with another body.

Moniteur Scientifique, No. 323, June 1, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Influence of the Motion (that is to say, swift movement in a certain direction) of a Source of Sound or Light upon the Sound or Light Emitted from the Object in Motion.—R. Radan.—This paper refers to the researches of Dr. Doppler, made in 1842; those of Dr. Buys-Ballot, made in 1845, upon the Dutch-Rhenish railway; and to the experiments made by M. Fizeau, and many other savants, on this subject.

Critical Essay on M. J. Raulin's Labours on Vegetation.—F. Papillon.—A very lengthy memoir.

NOTES AND QUERIES.

Bauxite.—If "J. B. S." will write to Dr. Lunge, South Shields, he will learn where this mineral can be obtained on a large scale.

Phosphate of Ammonia.—Will the gentleman who answered an enquiry regarding the manufacture of phosphate of ammonia oblige by giving details of the process, or state where full information may be obtained?—J. W. M.

The Metric System.—Observing Mr. Woodward's note in the *CHEMICAL NEWS* (vol. xxi., p. 273), I beg to suggest the following abbreviations, in place of those used by M. Evers, for the terms employed in the metric system of weights and measures:—Myria-metre, mym.; kilometre, kim.; hectometre, hem.; decametre, dem.; metre, m.; decimetre, dm.; centimetre, cm.; millimetre, mm.; square kilometre, sq. kim., or kim.²; square metre, sq. m., or m.²; square centimetre, sq. cm., or cm.²; stère or cubic metre, s. or c.m., or m.³; cubic centimetre, c.cm., or cm.³; cubic millimetre, c.mm., or m.m.m.; kilolitre, kil.; hectolitre, hel.; kilogramme, kigm.; gramme, gm.; decigramme, dgm.; centigramme, cgm.; milligramme, mgm. The Greek prefixes, which denote multiples, are thus represented by their first two letters; and the Latin prefixes, which denote sub-divisions, indicated by their first letter: gramme is gm., as gr. would still be required for grain.—J. CURRIE.

MEETINGS FOR THE WEEK.

MONDAY, June 20th.—London Institution, 8.

TUESDAY, 21st.—Ethnological, 8.

WEDNESDAY, 22nd.—Geological, 8.

THURSDAY, 23rd.—Royal Society Club, 6.30. Anniversary.

Zoological, 8.30.

FRIDAY, 24th.—Quekett Microscopical Club, 8.

TO CORRESPONDENTS.

Frank H. Storer is thanked for his valued communication. We hope for more anon, as promised.

J. Pattinson.—Thanks for your communication; it shall receive attention.

Hyposulphite of Soda alone is of no use in dyeing hair; it requires the addition of a lead solution. You had better write to the journal in which you saw the statement.

W. H. Walcott.—Received, with thanks.

J. F. Hill.—Apply to Roberts, Dale, and Co., Cornbrook Chemical Works, Manchester.

Chartism.—The reactions are very simple, and are to be found in every book on analysis.

J. Currie.—Mr. J. C. Morton's "Cyclopaedia of Agriculture" will probably meet your requirements; it is published in a vols. by Blackie and Son. Baxter's "Library of Agriculture," 2 vols. (Simpkin and Co.); "The Rural Cyclopaedia," by the Rev. J. Wilson, 3 vols. (Fullarton and Co.); and Doyle's "Cyclopaedia of Practical Husbandry," published by H. G. Bohn, are also good books on the subject.

BOOKS RECEIVED.

Researches on Diamagnetism and Magneto-Crystalline Action, including the Question of Diamagnetic Polarity. By John Tyndall, LL.D., F.R.S. London: Longmans and Co.

Notes of a Course of Nine Lectures on Light, delivered at the Royal Institution of Great Britain, April—June, 1869. By John Tyndall, LL.D., F.R.S. London: Longmans and Co.

Water Analysis: a Practical Treatise on the Examination of Potable Water. By J. Alfred Wanklyn, M.R.C.S., late Professor of Chemistry to the London Institution; and Ernest Theophrastus Chapman. 2nd Edition, Edited by E. T. Chapman. London: Trübner. 1870.

THE CHEMICAL NEWS.

VOL. XXI. No. 552.

ON THE AMMONIA COMPOUNDS OF PLATINUM.*

By WILLIAM ODLING, M.B., F.R.S.,
Fullerian Professor of Chemistry, Royal Institution.

FOR nearly a century past ammonia gas, discovered by Priestley in 1774, has been a subject of extreme interest to chemists. This ammonia gas, H_3N , is especially characterised by its property of uniting directly with hydrochloric acid gas, HCl , to form a solid deposit of sal-ammoniac, or hydrochloride of ammonia, $\text{H}_3\text{N.HCl}$.

In several important particulars, sal-ammoniac presents a remarkable similarity of behaviour to chloride of potassium: and by linking together the hydrogen of its acid with its ammonia so as to form the grouping $\text{H}_3\text{N.H}$ or H_4N , it may be regarded as the chloride of a composite metal ammonium, just as potassium chloride is the chloride of the simple metal potassium; thus:—

Ordinarily, when potassium chloride is subjected to the action of a weak current, no potassium, but only potash, makes its appearance at the negative pole; but if the negative pole be constituted of a drop of mercury, the electrolytically-liberated potassium remains dissolved in the mercury as potassium-amalgam, K_xHg_y . Similarly, when solution of sal-ammoniac is subjected to electrolysis, the negative pole being constituted of mercury, there is produced a bulky amalgam of ammonium $(\text{H}_3\text{N.H})_x\text{Hg}_y$; which, however, when no longer under the influence of the current, speedily breaks up into ammonia, hydrogen, and mercury. Ammonium-amalgam may further be produced on a large scale by the action of potassium-amalgam or sodium-amalgam on sal-ammoniac solution, thus:—

Another characteristic property of ammonia gas is its extreme solubility in water. By its dissolution it furnishes a liquid having many of the properties of aqueous potash, as, for example, the properties of affecting test-paper, of neutralising acids, and of precipitating metallic salts. And just as sal-ammoniac may be regarded as a chloride of ammonium, analogous to chloride of potassium, so may aqueous ammonia be regarded as a hydrate of ammonium analogous to hydrate of potassium, thus:—

But whereas chloride of ammonium, analogous to chloride of potassium, constitutes a definite body,—hydrate of ammonium, analogous to hydrate of potassium, has an inferential existence only. It is inferred to exist in solution from the reactions of the solution; but, under all attempts at extraction, it breaks up into ammonia gas and water, thus:—

But by far the most interesting circumstance with regard to ammonia is its property, so remarkably developed by Hofmann, of serving as a type from which compounds of the most varied character are derivable by substitution. Just, for example, as the hydrocarbon residue, or radical, ethyl, C_2H_5 , can replace the hydrogen of hydrochloric acid to form ethylic chloride, $\text{C}_2\text{H}_5\text{Cl}$, so can it also replace the hydrogen of ammonia to form ethylamine,

$\text{C}_2\text{H}_5\text{H}_2\text{N}$. This ethylamine constitutes a very volatile liquid, vapourising considerably even at ordinary temperatures. Its vapour closely resembles ammonia gas, but is distinguishable therefrom by its ready inflammability. Like ammonia, ethylamine combines directly with hydrochloric acid to form ethylamine sal-ammoniac, or hydrochloride of ethylamine, $\text{C}_2\text{H}_5\text{H}_2\text{N.HCl}$. Like ammonia, also, ethylamine is extremely soluble in water; and its solution, like that of ammonia, behaves in many respects as a definite hydrate, $\text{C}_2\text{H}_5\text{H}_2\text{N.H}_2\text{O}$, not obtainable, however, in the isolated state, but, like hydrate of ammonia, known only in the state of solution.

There exist, moreover, derivatives of ammonia in which a portion of its hydrogen is replaced, not by a monad, but by a diad residue or radical. Just, for example, as diad ethylene, C_2H_4 , replaces the hydrogen of two units of hydrochloric acid to form ethylenic chloride, $\text{C}_2\text{H}_4\text{Cl}_2$, so can it also replace, in part, the hydrogen of two units of ammonia to form ethylenamine, $\text{C}_2\text{H}_4(\text{H}_2\text{N})_2$ or $(\text{C}_2\text{H}_4)''\text{H}_4\text{N}_2$. This double ammonia unites with two units of hydrochloric acid to form the definite hydrochloride, $\text{C}_2\text{H}_4(\text{H}_2\text{N})_2.2\text{HCl}$, and with two units of water to form the equally definite, stable, isolable, volatile, crystallisable hydrate, $\text{C}_2\text{H}_4(\text{H}_2\text{N})_2.2\text{H}_2\text{O}$.

The hydrochloride and non-isolable hydrate of ethylamine being compared with the chloride and hydrate of the monad alkali-metal potassium, the hydrochloride and isolable hydrate of ethylenamine are similarly comparable with the chloride and hydrate of the diad alkali-metal, barium, thus:—

And hydrate of ethylenamine agrees with hydrate of barium, as well in being a powerfully alkaline base, as in being de-hydratable, not by the action of heat, but by indirect methods only.

Through the further researches of Hofmann, chemists are acquainted with ammonias and di-ammonias, in which, not only one-third, but two-thirds and three-thirds of the hydrogen are replaced by monad ethyl and diad ethylene respectively. With regard to these compounds, both in their properties and in the nature of the hydrochlorides and hydrates which they furnish, di- and tri-ethylamine correspond very closely to ethylamine; di- and tri-ethylenamine very closely to ethylenamine.

		Ethylamines.	Ethylenamines.

Although, in this way, the principal developments and ultimate establishment of the idea of ammonia as a type have resulted from investigations in organic chemistry, the idea itself appears to have originated, in the first instance, from investigations made in mineral chemistry; and especially from the investigation of compounds formed by the reaction of certain metallic salts and ammonia. Graham, indeed, had early represented certain compounds of metallic chlorides with ammonia as being metallicised sal-ammoniacs; but the notion of ammonia as a trihydric type, susceptible of three successive degrees of substitution, was first enunciated by Laurent, and was employed by that most original chemist to explain, among other matters, the constitution of different ammoniated compounds of platinum, discovered by Magnus, Gros, and Reiset successively. These compounds he represented as being salts of derived ammonias, in which different proportions of the hydrogen of ammonia were replaced by platinum.

Platinum is a moderately hard pewter-coloured metal, possessed of many singular properties. It was first recognised as a distinct metal by Wood, an assayer of Jamaica, in 1741. The mode of working it was discovered and practised by Wollaston early in the present century, and described by him in the *Philosophical Transactions* for 1829. Platinum is especially characterised by its high

* A lecture delivered before the Royal Institution of Great Britain, June 10, 1870.

specific gravity; by its low conductivity, dilatibility, and specific heat; by its high ductility and tenacity; by its facile divisibility and reducibility; by its curious absorptivity of certain gases, more especially hydrogen; by its difficult attackability by chemical agents; and by its infusibility at the highest furnace heats. And by each of these several properties, except, perhaps, its high specific gravity, is it suited to some special application in the arts.

Chemically, platinum is characterised by its high atomic weight, 197; and by its formation of two well-defined chlorides,—a perchloride, also known as platonic chloride, expressed by the formula $Pt^{IV}Cl_4$, and a protochloride, also known as platinous chloride, expressed by the formula $Pt^{II}Cl_2$. Platonic chloride occurs in crystalline dark orange masses, freely soluble in water. Platinous chloride forms an olive-brown amorphous powder, quite insoluble in water, but dissolving in hydrochloric acid to form an ochre-coloured liquid. In 1828, the late Professor Magnus, by supersaturating this liquid with ammonia, obtained a remarkable compound, containing the elements of platinous chloride and ammonia, and presenting itself as a dull green, usually crystalline, precipitate. This notable green precipitate has formed the subject of frequent investigation from then till now; and different views of its constitution, from time to time, have been put forward. But no one of these views has received a sufficiently general acceptance to warrant the designation of the compound in accordance therewith; so that, from the period of its discovery down to the present day, it has ever borne the honoured name of its discoverer, and been known as the green salt of Magnus.

Some time after, Gros, in 1838, by treating the salt of Magnus with nitric acid, obtained a peculiar series of pale yellow, or colourless, platin-ammonia compounds. Next in 1840-44 *et seq.*, Reiset and Peyrone, by acting on the salt of Magnus, or on platinous chloride itself, with ammonia, obtained, independently of each other, two additional series of compounds, having relations of metamorphosis both with one another and with the foregoing series of Gros. Then, in 1846, Raewsky, by acting on the salt of Magnus with nitric acid, obtained yet another series of compounds, differing from those furnished to Gros by the same reagent.

But the formulæ attributed by Raewsky to the salts which he had just discovered were inconsistent, both with Laurent's view of ammonia as a type, and with other views of chemical constitution which those illustrious fellow-workers, Laurent and Gerhardt, shared in common. Accordingly, Gerhardt, in 1848, subjected Raewsky's formulæ—notwithstanding their corroboration by a Committee of the Academy—to a most trenchant criticism; and, after supplementing his criticism by laboratory research, published, in 1850, his celebrated memoir "On the Ammoniacal Compounds of Platinum." In this memoir, he established the existence of another, entirely new, series of platin-ammonia compounds; he showed, by experiment, the simple relationship in which the salts of Raewsky stand to the salts of Gros; and he set forth a complete, self-consistent, scheme of viewing the several series of platin-ammonia compounds in their relations to ammonia and to one another.

Since the publication of Gerhardt's memoir, further important contributions to the knowledge of platin-ammonia compounds have been made by different chemists, especially by Buckton, Hadow, and Thomsen. But neither before nor since has any complete general scheme of the constitution of this class of bodies been put forward. Nevertheless, the scheme of Gerhardt, though always treated with respect, has never met with general acceptance, and nowadays, at any rate, is open to very serious objections.*

* Gerhardt's own base platinamine, for instance, is represented by the certainly improbable formula, pt_2H_2N or $Pt^{II}H_2N$, and its hydrochloride by the yet more improbable formula, $pt_2H_2N \cdot 2HCl$; in which the unit of a mon-ammonia is represented as combined with two units of hydrochloric acid, and by which the entire chlorine of the salt is represented as fulfilling one and the same function.

The attention of the writer having, of late, been directed to the study of these compounds, he has succeeded in differentiating the simplest of the platinum sal-ammoniacs from several allied and isomeric bodies with which it had before been confounded; and in obtaining from it the corresponding hydrated base of the series. He has also obtained some reactions of interest with bodies belonging to the more complex series; and, as a general result of his inquiries, has ventured to put forward a new scheme of regarding the entire group of bodies. This scheme is based on the recognition of two principal facts or propositions:—

1. The different platin-ammonia compounds are produced, in the first instance, from platinous chloride, $PtCl_2$; and just as the platinum of this compound possesses the property of taking up two additional proportions of chlorine, so as to furnish the platonic compound, Cl_2PtCl_2 , or $Pt^{IV}Cl_4$, so also does the platinum of the different ammoniated bodies obtained from platinous chloride possess the property of taking up two proportions of chlorine, or its equivalent of other negative radical, so as to furnish platonic compounds corresponding to the original platinous compounds respectively. Hence, the division of platin-ammonia compounds into the two classes of platinous and platonic; the compounds of the former, differing in constitution from those of the latter class, just as platonic differs from platinous chloride, by a direct fixation of chlorine.

2. The monad residue, or radical amidogen, H_2N , is capable of becoming the monad radical ammon-amidogen, $H_2N \cdot H_3N$, or H_5N_2 , just as the monad radical methyl, H_3C , is capable of becoming the monad radical methylen-methyl or ethyl, $H_3C \cdot H_2C$ or H_5C_2 .* Viewing sal-ammoniac, $H_3N \cdot HCl$, as the analogue of methylic chloride, H_2CHCl , the difference is noticeable that, while the ammonia both of sal-ammoniac and ammon-amidogen is easily separable, the methylen both of methylic chloride and methylen-methyl is inseparable from the remaining constituents of the respective compounds. Hence, the distinction between the two classes of amic and ammon-amic platinum compounds, the latter differing from the former by an actual addition of diad ammonia, much as ethylic differ from methylic compounds by a virtual addition of diad methylen. The parallelism is indicated in the under-written formulæ for methylic chloride and ethylic chloride, sal-ammoniac and ammon-amidochloride of silver, respectively—

The group of platin-ammonia compounds is thus divisible into the two classes of platinous and platonic; and each of these again into the two classes of amic and ammon-amic compounds. To these four classes must yet be added a fifth sub-class of di-platonic compounds, including the nitrate-chloride of Raewsky, and the subsequently-discovered nitrate of Gerhardt and chloride of Hadow. The scheme of the constitution of the entire group, in accordance with the writer's views, is exhibited in the accompanying table of the principal chloride, hydrate, nitrate, and nitrite compounds.

PLATINUM BASES AND SALTS (PROPOSED SCHEME).

Platosamine.

Amo-platosamine (Reiset's).

Amo-platinamine (Gros's).

Platosamine.

The hydrochloride is obtainable by direct action of platinous chloride, $\text{Pt}''\text{Cl}_2$, on ammonia, just as ethylenamine hydrochloride is obtainable by direct action of ethylenic chloride, $(\text{C}_2\text{H}_4)''\text{Cl}_2$, on ammonia; and, in both reactions, the two compounds are each accompanied by various other products. The parallelism, in constitution and properties, of the two compounds and of their corresponding hydrates is complete—

Hydrochloride of platosamine, in its pure state, has a dull, very pale, primrose colour, approaching almost to white. It is very insoluble in cold, considerably more soluble in hot water.* From its concentrated hot solution it is usually deposited as a flocculent-looking, though really crystalline, or partly crystalline, precipitate; and by slow cooling of the solution, it may be obtained wholly in the form of distinct needles. The base is obtained from the hydrochloride, through the intervention of the sulphate, by decomposing the latter with baryta water. It is extremely soluble in water, and readily crystallisable. It furnishes a solution manifesting a strongly alkaline reaction, liberating ammonia from its salts, neutralising acids, absorbing carbonic acid from the air, and decomposing metallic salts—the precipitates thrown down being, however, for the most part double compounds.

The base and other soluble platosamine compounds are characterised by giving with hydrochloric acid a precipitate of the hydrochloride, which, when formed in this way, is almost always yellow and crystalline. All platosamine compounds, including the hydrochloride, exhibit the platinous property of absorbing chlorine, and hence of decolourising a mixture of hydrochloric acid and permanganate, to yield platinamine compounds; and they all, including the hydrochloride, dissolve in gently-heated ammonia, to yield their corresponding amo-platosamine compounds.

Amo-platosamine.

The hydrochloride of this series, unlike that of the preceding, is freely soluble in water. It is a beautiful salt, crystallising usually in a mass of interlaced lengthy needles. It is made by dissolving platinous chloride, salt of Magnus, or the above platosamine hydrochloride, in aqueous ammonia at a gentle heat. The hydrated base is obtained from it, as is the preceding hydrated base from the preceding hydrochloride. The so-produced hydrate corresponds in its general properties with the above hydrate of platosamine, than which, however, it is far more powerfully alkaline. From different metallic salts it throws down the respective metallic hydrates.

Amo-platosamine salts, like those of platosamine, exhibit the platinous property of decolourising a mixture

of hydrochloric acid and permanganate, of directly absorbing chlorine or bromine, and also of directly absorbing nitric peroxide, to furnish amo-platinic compounds." The resulting amo-platinic chloro-chloride occurs as a pale yellow, the nitro-chloride as a pale green, and the nitro-nitrate as a pale blue precipitate. Amo-platosamine is further distinguished from platosamine by the free solubility of its hydrochloride, and by the reaction of this salt with platinous chloride solution to throw down the green salt of Magnus.

Platinic Compounds.

The most characteristic of the salts of platinamine is the chloride $\text{Cl}_2\text{Pt}'''(\text{H}_2\text{N})_{2.2}\text{HCl}$. It is best made by addition of permanganate, in very slight excess, to a hot solution of platosamine hydrochloride, acidified with hydrochloric acid. It is a beautiful bright yellow salt, dissolving sparingly in cold, moderately, though, on account of its density, somewhat slowly, in boiling water; and crystallising readily on cooling in isolated octohedrons or square plates. It reacts with excess of ammonia, at a gentle heat, to form the insoluble chloride of amo-platinamine. Its chlorine, like that of the amo-platinic chloride, is evidently in two different conditions of attackability by reagents, such as alkalis and silver salts. The hydrate of platinamine is obtained from the hydrate-nitrate, by means of ammonia, as a neutral, almost insoluble, bright yellow, crystalline precipitate.

The best known salt of amo-platinamine is the chloro-nitrate, $\text{Cl}_2\text{Pt}'''(\text{H}_5\text{N}_2)_{2.2}\text{HNO}_3$, obtained by treating the salt of Magnus, or preferably the hydrochloride of amo-platosamine, with nitric acid. It is moderately soluble in water, and crystallises therefrom in brilliant white flat prisms. Its chlorine is not immediately recognisable by nitrate of silver; and is only partially precipitable thereby, even after long boiling. Its solution yields, with ammonium chloride and sodium sulphate, crystalline white precipitates of the chloro-chloride and chloro-sulphate respectively.

The most familiar salt of amo-di-platinamine is the chloroxy-nitrate, $\text{Cl}_2\text{OPt}_2'''(\text{H}_5\text{N}_2)_{4.4}\text{HNO}_3 \cdot \text{Aq}$. It is best made by boiling the chloro-nitrate or chloro-chloride of amo-platinamine with nitric acid and nitrate of silver. It presents considerable resemblance to the chloro-nitrate of amo-platinamine, but its solution is not disturbed either by sulphate of sodium or chloride of ammonium. It yields, moreover, with platinous chloride solution, a moss-like coppery precipitate which is highly characteristic (Hadow).

NOTE ON THE
TEMPERATURE AND HEATING-POWERS OF
FLAMES.†

By W. M. WATTS, D.Sc.

MR. WATTS has forwarded to us the following remarks on Messrs. Silliman and Wurtz's paper "On the Temperatures of Flames," which appeared in our last and previous numbers, in which certain conclusions on some practical points of importance are stated.

The following numbers are correctly given as representing the amounts of heat evolved by the complete combustion of equal volumes of the following gases:—

Hydrogen	34462
Carbonic oxide	33642
Marsh gas	104504
Olefiant gas	166012

* The reaction of amo-platosamine compounds with nitric peroxide was discovered by Hadow, but received from him a different interpretation.

† From the *Philosophical Magazine*, May, 1870.

* The orange-yellow, scaly, far more soluble hydrochloride, obtained by dissolving salt of Magnus in sulphate of ammonia solution, is a distinct compound.

But the conclusion that the heating-power of olefiant gas is greater than that of an equal volume of hydrogen is condemned as erroneous; and the authors give, as the result of their investigations, "that the powers of the flames of pure hydrogen and pure olefiant gas, even when used to the greatest advantage, to heat water below its boiling-point are almost or quite identical."

There seems to be, throughout the paper, a confusion between the heating-power of a gas and the temperature of its flame in air.

It is quite true that, because the specific heat of steam (which is one of the products of combustion of olefiant gas) is greater than the specific heat of carbonic anhydride (the only product of combustion of carbonic oxide), the calculated flame-temperature of the latter gas is higher than that of the former; but, for the very same reason, if these gaseous products of combustion expend their heat in raising the temperature of water, the greatest effect will be produced by the olefiant gas, although the temperature of its flame is not so high as that of the flame of carbonic oxide. If the gases give up the whole of their heat to the water, it is obvious that the calorific effects must be precisely in the ratio of the numbers already quoted; and, even if they escape at a temperature considerably above 0°C ., their relative effects will be nearly the same. If we suppose the products of combustion to have a temperature of 200°C . when they escape, the following quantities of heat will still be available by the combustion of equal volumes of carbonic oxide and olefiant gas:—

Gas burnt..	Lbs. of water raised from 0°C . to 100°C .
14 lbs. carbonic oxide	314
14 lbs. olefiant gas	1546

And these numbers are almost exactly in the same ratio as the numbers 33642 and 166012. We conclude, therefore, that the numbers quoted (vol. xxi., p. 282), in which, according to Messrs. Silliman and Wurtz, "several most grave errors are involved," do, in reality, strictly represent the heating-effects of the different gases when employed to the greatest advantage, in heating water below 100°C .

The omission of the correction for the latent heat of steam in Bunsen's original calculation of the temperature of the hydrogen-flame has been already pointed out by Dibbits.*

In the calculation of the temperature of the hydrogen-flame given in this paper (p. 283), there is also an error in assigning to liquid water the specific heat 0.4805, instead of 1. The formula should be—

$$x = \frac{34462 - 9(637 - 48.05)}{4.3245} = 6743^{\circ}\text{C}.$$

Another of the conclusions arrived at in this paper is erroneous, viz., "That, of all known gases, the highest calorific effects,† under ordinary atmospheric conditions, are obtainable from carbonic oxide, whose calorific value, above 100°C ., is about 3000°C ."

The flame of cyanogen is hotter than that of carbonic oxide, the calculated temperature of the flame of cyanogen in air being 3519°C ., and in oxygen no less than 10557°C . It must be remembered, however, that these results of calculation in no way express the actual flame-temperatures. The calculated temperature of the oxy-hydrogen-flame is 6743°C .; but the experiments of Deville‡ and Bunsen|| agree in fixing between 2500°C . and 2800°C . The following are the calculated and experimental flame-temperatures of certain gases; it will be seen that the flame of cyanogen is shown by experiment also to have the highest temperature:—

	Calculated. $^{\circ}\text{C}$.	Experimental. $^{\circ}\text{C}$.
Hydrogen in air	2701	2024
" " oxygen	6743	2844
Carbonic oxide in air ..	2996	1997
" " oxygen	7067	3033
Cyanogen in air	3519	3297
" " oxygen	10557	—
Olefiant gas in air	2727	—
" " oxygen	8606	—

ON THE DESCENT OF GLACIERS.*

By The Rev. HENRY MOSELEY, M.A., F.R.S.,
Canon of Bristol, and Instit. Imp. Sci. Paris Corresp.

(Concluded from p. 278.)

All Alpine travellers, from De Saussure to Forbes and Tyndall, have borne testimony to the intensity of the solar radiation on the surfaces of glaciers. "I scarcely ever," says Forbes, "remember to have found the sun more piercing than at the Jardin." This heat passes abruptly into a state of intense cold when any part of the glacier falls into shadow by an alteration of the position of the sun, or even by the passing over it of a cloud. Now the Mer de Glace moves faster by day than by night. Its mean daily motion is twice as great during the six summer as during the six winter months. The connection between its rate of motion and the external temperature is most remarkable. It has been carefully observed, and the results as recorded by Professor Forbes leave no doubt of the fact, that no change of external mean temperature is unaccompanied by a corresponding change of glacier motion. From this it follows that the two are either dependent on some common cause, or that the one set of changes stands in the relation of a cause to the other. That both sets of phenomena—the changes of the sun's heat, and the changes of glacier motion—should be due to some common independent cause, seems impossible. We are forced, therefore, on the conclusion that one is caused by the other. And as the changes in the glacier motion cannot cause the changes of solar heat, it must be the changes of solar heat which cause the changes of glacier motion. The sun is obviously master of the glacier. Nor is this to be considered a startling or improbable conclusion. Heat is but another form of mechanical power. This power is constantly streaming into the glacier; for ice is diathermanous. It is readily penetrable by luminous heat. This has been shown by Tyndall, who, having sent a beam of heat through a block of Wenham Lake ice, saw its course starved by the dilations of the ice. I have, moreover, myself obtained an ice lens by causing ice to be turned in a lathe to a spherical surface by means of a templet of iron. Through this lens the rays of the sun streamed in abundance, and were concentrated in its focus with such intensity as to burn the hand and instantly set fire to a match. There can be no doubt, therefore, that the rays of the sun, which in those Alpine regions are of such remarkable intensity, find their way into the depths of the glacier. They are a power, and there is no such thing as the loss of power. The mechanical "work" which is their equivalent, and into which they are converted when received into the substance of a solid body, accumulates and stores itself up in the ice under the form of what we call elastic force, or tendency to dilate, until it becomes sufficient to produce actual dilatation of the ice in the direction in which the resistance is weakest, and by its withdrawal to produce contraction. How much heat entering the surface of a glacier is necessary to this result has been made the subject of calculation. Supposing the depth of the ice to

* Pogg. Ann., vol. cxxii., p. 497.

† Read "flame-temperatures."

* Read before the Royal Institution of Great Britain, May 13, 1870.

be the same as that at the Tacul, its motion at different depths that which Tyndall found it to be there, and its surface motion that which he measured lower on the Mer de Glace at Les Ponts, and supposing the resistance to shearing of ice to be 75 lbs. per square inch; then the mechanical work, which acting within the mass is necessary to put the glacier in motion, as it actually moves, is $6\frac{1}{2}$ units of work per square inch of the surface of the glacier per day.* Now this quantity of work would be supplied by 0.0635 heat-unit entering the ice per square inch of surface per day and diffusing itself through it, each heat-unit being the heat necessary to raise 1 lb. water by 1° F. Far more than this heat probably passes the surface and enters into the ice of a glacier on days such as that when the motion was observed which serves as the basis of these calculations.

But *how* does this mechanical power, which thus streams continually into a glacier when the sun shines on it, compel its descent?

The fact of the descent of a sheet of lead when placed upon the inclined surface of a roof, however low the pitch, especially in summer, has long been known; I myself first observed it on the southern side of the roof of the Choir of the Bristol Cathedral, in 1855. I have verified it by the following experiment:—I fixed a deal board 9 feet long and 5 inches broad to the southern wall of my house, so as to form an inclined plane, and upon it I placed a sheet of lead, turning its edges down over the side edges of the board, and taking care that it should not bind upon them, but be free to move with no other obstruction than that which arose from its friction. The inclination of the board was $18^{\circ} 32'$, the thickness of the lead $\frac{1}{4}$ th of an inch, its length 9 feet, and its weight 28 lbs. The lower end of the board was brought opposite to a window, and a vernier was constructed, which could be read from within, and by which the position of the lead upon the board could be observed to the rooth of an inch. I began to measure the descent of the lead on the 16th of February, 1858, and recorded it every morning between seven and eight o'clock, and every evening between six and seven o'clock, until the 28th of June. I have preserved all these observations. In the night, between sunset and sunrise, the lead scarcely descended at all. It was on days when the thermometer in the sun varied its height rapidly and much—as on bright days with cold winds, or when clouds were driven over the sun—that the descent was greatest. So remarkable, indeed, was this the case, that every cloud which shut off the sun for a time from the lead, and every gust of wind which blew upon it in the sunshine, seemed to bring it down a step. On such days it would descend from $\frac{1}{4}$ to $\frac{1}{2}$ inch. On the contrary, when the sky was open and clear, and the heat advanced and receded uniformly, the descent was less, although the difference of the extreme temperatures of day and night might be greater. It was least of all on days of continuous rain. The sun was the obvious cause of the descent of the lead. It was master of the lead, as it is of the glacier. A dilatation and contraction of it was caused by the passage into it, and the withdrawal, of the sun's radiant heat, and this dilatation and contraction of the lead caused it to descend. Why it should do so may be easily explained.

Let A B, Fig. 1, be an elementary plate of the solid, and conceive it to be divided into an infinite number of equal elements by planes perpendicular to its length. Let x be a point so taken in it that, if it were divided in x, the thrust necessary to push the part x A up the plane would equal that necessary to push x B down it. Let an element at x be imagined to have its temperature so raised as just to equal this thrust; and let the temperatures of all the elements in x A, beginning at x, be equally raised in succession. Each will thus be dilated more than the one before it, because its dilatation will be opposed by a less resistance; and the displacement, A A₁,

of the extremity upwards will equal the sum of these several dilatations. In like manner, if the same temperature be added to the elements of x B in succession, beginning from x, each will be dilated more than the one before it, and the displacement, B B₁, of the extremity B downwards will equal the sum of these several dilatations. The point x will obviously be nearer to A than to B, because the same thrust of dilatation of the element at x would not be able to push so great a length of the bar up the plane as it would down it.

In this state of the temperature of the plate, let a point, x₁, be taken such that, if it were divided there, the strain necessary to pull the part x₁ A₁ down the plane would just equal that necessary to pull x₁ B₁ up it. Let the temperature of the element at x₁ be so diminished as by its contraction just to produce this strain, and let the temperatures of all the elements from x₁ A₁ in succession be similarly reduced. Each will contract more than the one before it, because a less resistance will be offered to its contraction; and the displacement A₁ A₂ of A₁ down the plane will equal the sum of these separate contractions. In the same way the displacement B₁ B₂ of B₁ up the plane will equal the sum of the separate contractions of the elements of x₁ B₁. The point x₁ will be farther from A₁ than B₁, because the same strain of contraction of an element at x₁ would pull a greater length of the bar down the plane than up it.

It is by the dilatation of the greater length of the plate x B favoured by its weight that the extremity B is

FIG. 1.

displaced down the plane when the temperature is raised; whilst it is by the contraction of the less length, x₁ B₁, against its weight that it is displaced up the plane when the temperature is lowered. The extremity B is, therefore, more displaced down the plane by a given raising of the temperature than it is displaced up it by a corresponding lowering. On the whole, therefore, the extremity B is made to descend the plane to B₂ by a given alternation of temperature. It is by the dilatation of the less length, x A, that the extremity A is displaced up the plane, and by the contraction of the greater length, x₁ A₁, that it is displaced down the plane. It is, therefore, less displaced up by dilatation, than it is down by contraction, and on the whole it descends to A₂ by a given alternation of temperature. Both the extremities A and B of the plate are, therefore, made to descend when it is subjected to a given elevation and then to a corresponding depression of its temperature; that is, the whole plate is made to descend from A B to A₂ B₂.

Now, the theory of the descent of glaciers, which I have ventured to propose, is that they descend, as the lead in this experiment does, by reason of the passage into them and the withdrawal of the sun's rays, and that the dilatation and contraction of the ice so produced is the proximate cause.

There is no substance the dilatation or contraction of which, by changes of temperature, is more thoroughly and accurately known than that of ice. Experiments were made upon it by three independent observers, at the observatory of Pultowa, in the winters of 1845 and 1846, between the temperatures of 0° R. and 28° 82' R., from which it resulted that ice is by far the most dilatible of all known solid substances, being nearly twice as dilatible as lead. These experiments have been described by Baron W. Struve, in the "Transactions of the Academy of St Petersburg."

The ice of a glacier behaves itself in its descent exactly as the lead did in my experiment.

* Proceedings of the Royal Society, January, 1869, p. 207.

It has been argued in opposition to this theory that the temperature of the ice of glaciers is, by the observations of Agassiz, but very little below 32° , and that if radiant heat found its way into it, it would not expand, but melt it. To this there is the obvious answer that radiant heat does find its way into ice as a matter of common observation, and that it does not melt it, except at its surface, and therefore that it *does* dilate it. Blocks of ice may be seen in the windows of ice shops with the sun shining full upon them, and melting nowhere but on their surfaces. And the experiment of the ice-lens shows that heat may stream through ice in abundance—of which a portion is necessarily stopped in the passage—without melting it, except on its surface. My theory supposes that the ice beneath the surface of a glacier is a *solid*. That is all.

Being a solid, and receiving into its substance heat—that work—in great quantities, that work (by the principle of the conservation of force) cannot but be stored up in it, under the form of “potential energy,” and wherever it is present, produce a tendency to dilatation. When that tendency takes effect, it is in the direction of the least resistance to the dilatation of that part. It matters not whether the temperature of the ice be below 32° or above it, provided only that the condition of solidity be satisfied. Being a solid, it cannot but dilate and contract under the variations of temperature to which it is subjected; and dilating and contracting, it cannot but descend. To show that the ice of a glacier does not dilate when heat is received into it, it would be necessary to show it not to be subject in this respect to a law common to all other solid bodies.

Great alternations of temperature are not necessary to cause the motion of a glacier. A succession of *small* alternations produces the same effect as one great one. Their effect is cumulative. Alternations backwards and forwards, of 2° each, six times repeated, would carry the glacier (under certain assumed conditions) as far down as a single alternation of 12° .

The observations of Agassiz on the temperature of the ice of the Aar glacier in 1841-1842, were made in borings from 15 to 200 feet deep. Thermometers placed in these borings never fell below 0.3° C., although the external temperature descended at night to 5° or 6° C. Commonly they showed exactly zero.* Nothing can, however, be concluded from these experiments, because the thermometers were not *frozen into the ice* of the glacier, or the mouths of the borings so effectually stopped as to prevent the access of air or the percolation of water from the disintegrated ice near the surface. The maintenance of a constant state of humidity in the air of the boring not being thus provided against, the included thermometer could not but remain at zero, however low might be the temperature of the surrounding ice. For the water of the contained air freezing on the sides of the boring (like hoar frost) would raise the temperature around the bulb, by the latent heat set free in freezing, to zero, C. And the humidity of the air being continually renewed, this process would always go on.

“A thermometer is, in short, incapable of taking the temperature of ice, unless that ice be dry.”† These are the words of that eminent man Principal Forbes in the last (I think) of his papers on the subject of glaciers.

On a Friday evening like this, eight years ago, another eminent man, whose loss to science we all deplore, addressed the audience then assembled here on the subject on which I have now been addressing you. He possessed every accomplishment for the investigation of it, and had studied it long and successfully; he was versed in physics, and was an able and original mathematician. I speak of Mr. William Hopkins, whose name will always be held in honour by reason of his many contributions to the science of glaciers, and especially because of the explanation he first gave of the formation of crevasses. In the introductory part of the discourse which Mr. Hopkins

then delivered he “insisted on the necessity of a more exact definition of terms and more accurate modes of mathematical reasoning than those which had up to that time characterised the discussion of glacial phenomena.”

That, on the necessity of which he insisted and for which he laboured, I also have laboured for. I have sought to bring the discussion of glacial phenomena out of the wide region of scientific opinion, and place it in that of exact science. That work is, however, still far from being completed. Life, too, is short, and the power to pursue studies such as these is sometimes shorter in duration than life itself. But other workers are behind.

PROCEEDINGS OF SOCIETIES.

CHEMICAL SOCIETY.

Thursday, June 16th, 1870.

Professor WILLIAMSON, F.R.S., President, in the Chair.

THE following gentlemen were elected Fellows:—L. A. Lucas and A. W. Bickerton.

Mr. JAMES BELL read a paper “On Fermentation.”

A series of experiments has been instituted, and is still in progress, to determine the forms of natural ferment which albumen, derived from different sources and under various conditions, will give rise to.

Albumen of egg was introduced into a cane-sugar solution, and the mixture allowed to ferment at a temperature of 75° F. Fungoid cells, different from those of yeast, were formed, and possessed of very little fermentative power, inasmuch as only 0.2 per cent of alcohol were produced in this sample.

Albumen of flour and malt, in a cane-sugar solution, gave rise to the development of a fungoid mycelium, and consequent production of cells and spores similar to those obtained by albumen of egg. These, too, were of very limited fermentative power. The albumen in this case was prepared by coagulation, and then by precipitation. When albumen of the first kind was brought into the sugar solution, the liquid very soon contained parasites, and became rapidly acid. If albumen obtained by precipitation with alcohol was employed, the solution, even after a week, was free from parasites, and also of acidity.

Cold water extracts of flour and malt were added to cane-sugar solution, which also contained some glucose. The extract, on addition of cane-sugar, was converted into mucilage; and the change is permanent in flour-extracts, but extracts of barley-meal possess great power to produce the yeast-cells, which act upon the mucilage, and resolve a portion of it into alcohol and carbonic acid. The development of the yeast-cells in the mucilage is a most interesting sight: the cells, as they multiply, are prevented from separating, on account of the thickness of the solution, and thus remain clustered together.

Cold water extracts of grain abound with microscopic parasites, which soon set up a strong action, thereby giving rise to the production of acid, and doubtless, also, to the transformation of the cane-sugar into mucilage. Boiling destroys these parasites, prevents in a great measure the production of acid, and subsequently yields more alcohol. This conclusion was arrived at after many and varied experiments.

When “pus” was employed as ferment, a fungoid organism, similar to that obtained by albumen from flour and malt, was developed in the solution, which likewise possessed very little fermentative power.

The fermentative properties of two moulds, the blue mould from moist malt and the mould from lemon-juice, were next investigated in a glucose solution. Both proved good ferments.

* *Bulletin de Geneve*, tom. 44, p. 349.

† *Forbes, Phil. Mag.*, March, 1859.

In order to compare the relative fermentative power of the yeast-plants of malt and the grape, the following experiments were instituted:—

To a solution capable of giving 16 per cent alcohol, brewers' pressed yeast was added successively. The limit was reached on the sixteenth day; but the experiment was carried on for upwards of thirty days, when the alcohol in the liquid amounted to 15.91 per cent. When the extreme point was reached, the yeast-cells became contracted and shrivelled; but, when they were transferred to a fresh sugar-solution, they recovered their vitality. In several cases, glucose was added to the cane-sugar solution; and it was here observed that, in the presence of an excess of glucose, comparatively less alcohol was obtained: the alcohol and glucose combined seem to act as an antiseptic.

To the must from English hot-house grapes a known quantity of glucose was added, and the liquid, together with the greater part of the husks, was left to ferment at 65° F. The fermentation ceased in about twenty-three days. Another sample was permitted to ferment at 75° F.; and here all action ceased on the sixteenth day. To a third sample such amount of glucose was added as to bring the glucose naturally existing in the juice up to 40 per cent. In this case, the beginning of the fermentation was delayed much beyond the usual time; and the quantity of alcohol obtained was less than in a case where less glucose had been added.

In all cases the wine-ferment proved to be of greater fermentative power than the malt-ferment.

From all these experiments Mr. Bell deduces the conclusion that it would be advantageous to add to grape-juice some glucose, so as to assist the exhaustion of the must of its fermentative element, and to impart thus to the wine a greater keeping-power. In some instances the fermentation was started in the grape-juice by brewers' yeast: the amount of alcohol here obtained was less than in the cases where the action was caused by the natural ferment of the grape-juice.

Finally, Mr. Bell instituted some experiments to ascertain the influence of change of soil; and the results in connection with the observations made in some of the above experiments lead to the inference that the various ferments have their favourite soils.

The PRESIDENT, in asking the Fellows to vote their thanks to the author, gave a brief *resumé* of the state of knowledge we at the present day possess of the yeast-plant. Though called a "plant," the yeast organism appears in all its functions rather animal than vegetable. The products of its secretion are less complicated than those it takes in. It does not, like plants, require light for its vital process; neither does it absorb heat, but, on the contrary, gives such off. Prof. Williamson then, alluding to Leibig's recent memoir, observed that this distinguished chemist has entirely dropped his ancient notions regarding fermentation, though he somewhat successfully criticised some of Pasteur's statements.

The next paper read was, "*On Organic Matter in Water*," by Dr. HEISCH.

The author was, some time ago, called on to assist a large manufacturer of lemonade, who suddenly found it impossible to make lemonade that would keep; after a day or two it became turbid, and its odour anything but agreeable. On examining the liquid under the microscope, it was found full of small spherical cells, with, in most cases, a very bright nucleus.

After investigating all the materials employed, the water was detected to bear the fault. On putting a few grains of the purest crystalline sugar into some of the water, it became turbid in a few hours, and contained the cells previously described.

On enquiry, Dr. Heisch found that some digging had been going on in the neighbourhood of the well from which the water came; and that, through this circumstance, some drainage must have got into the well. This led the experimenter to try various samples of waters in

the same manner; and, in every case where diarrhoea or other mischief could be traced to the use of a certain water, when that water was treated with sugar, the same cells made their appearance usually within 24 hours, if kept at 60° to 70°, and plenty of light was admitted to the bottle containing the fermenting liquid.

Believing sewage to be the source of these cellular germs, Dr. Heisch mixed a minute quantity of sewage with a sugar-solution which had been previously ascertained to be free of cells, and found the solution very soon to contain those germs. A number of experiments were made to find out whether other substances than sewage or sewage-water were capable of producing organisms of similar kind when placed into a sugar-solution; but, though in a few cases some growths were produced, they never resembled the cells originated by sewage. In all the experiments with sewage, where the particular cells made their appearance, a butyric odour also was perceptible. Filtering the water through the finest Swedish paper does not remove the germs. Boiling for half an hour in no way destroys their vitality. Filtration through a good bed of animal charcoal seems to be the only effectual mode of removing them; but it is necessary to air the charcoal from time to time, else it loses its purifying power.

The author is at present engaged to ascertain what substances are capable of retarding or preventing the development of these germs. As to the conclusions derived from the above observations, Dr. Heisch thinks that wherever the described germs occur in water they are distinct evidence of sewage-contamination.

Mr. PERKIN read a letter from Prof. Strecker, wherein he claims the priority of having published the true formula of alizarine as early as 1866, a priority which had been ignored by Mr. Perkin in his recent lecture on alizarine. Mr. Perkin said that this omission is due only to a slight oversight; he never intended to deprive Prof. Strecker of his merits.

Mr. W. D. HERMAN communicated a paper "*On the Methods for the Determination of Carbon in Steel*."

The author, whilst studying the process for determining carbon in steel known as Eggertz's Colorimetric Method, observed certain irregularities and imperfections in its practical working. One of the most serious difficulties in this process, arising from the instability of the standard solution of burnt sugar, had been overcome for some time past by Mr. Valentin, who employed, with perfect success, a solution of sulphindigotic acid which had undergone decomposition by exposure to sunlight. Although much was gained by substituting a stable for an unstable solution, it was still apparent that the colour of the solution of various samples of steel in nitric acid, especially of those containing larger quantities of carbon, did not always coincide in tint with the new colour-standard.

These difficulties led the author to corroborate the colorimetric results by other methods of analysis. He first tried Elliott's method (described in the new edition of Fresenius's "*Quantitative Analysis*"); but the washing of the carbon on the asbestos filter was found to be too tedious, and the whole process requiring great care and constant attention. A direct method of analysis was therefore tried, and the iron burnt in a stream of oxygen. The heat produced by this process was, however, so great that the best glass tubes cracked on cooling. This obstacle was surmounted by using a platinum tube, which is connected with the glass apparatus containing the soda-lime, &c., by means of a brass tube tinned inside, and the latter is joined to the platinum tube by means of a bayonet-joint. The steel to be analysed is previously softened, and then reduced to fine filings, by means of a single-cut file, which has the advantage of bringing to a minimum the danger of breaking off the teeth, and also of producing filings in fine shreds, a condition very favourable to rapid and complete oxidation. The time required for the oxidation of about 2 grms. of steel was usually forty minutes. The amount of ferric oxide left

behind after the combustion of the carbon may be weighed, and its weight, coinciding with the amount required by theory, serves then as a criterion of the completeness of the combustion.

The following table contains a *resumé* of the means of the results obtained by the different methods employed by Mr. Herman for determining the carbon in various samples of steel:—

	I.	II.	III.	IV.	V.	VI.	VII.	VIII.
By Eggertz's colorimetric method . . .	1'3190	0'7890	0'7010	0'5870	0'4860	0'3490	0'2830	—
By direct combustion of filings in oxygen . . .	1'1656	0'7602	0'6350	—	—	0'3594	0'2730	0'9215
By Elliott's methods . .	1'2480	0'8065	0'7240	0'6701	0'5025	0'4772	0'3490	0'9427

From all the foregoing observations it follows:—

1. That Eggertz's process cannot be employed when the amount of carbon is large, and is required to be known with accuracy.

2. That the method of combustion in oxygen is preferable as being direct, expeditious, giving accurate results, and allowing to ascertain readily whether the combustion has been a complete one.

In conclusion, the author expressed his thanks to Mr. Valentin for the valuable advice received whilst conducting these experiments.

ROYAL IRISH ACADEMY.

At a meeting held on Monday, June 13th, at the Academy House, the Rev. Prof. JELLETT in the chair, Dr. SIGERSON read a paper on the "*Microscopic Appearances obtained from Special Atmospheres*."

His lecture was illustrated with large diagrams representing some of the objects discovered. In "iron-factory air" he found carbon, ash, and iron: the iron was discovered to be hollow balls, averaging 1-2000th part of an inch in diameter, their shells being only 1-30,000th part of an inch; and the iron was found to be translucent. In "shirt-factory air" there were filaments and fragments of linen and cotton, with minute eggs. The air of threshing and oat mills had fibres, fragments, starch-grains, and spores. "Scutch-mills," from the character and the spongy, spiky dust and its effects, he declared to be human slaughter-houses: by a suggested alteration, the workers could be kept free of the dust, and many lives saved. In the air of the printing-offices antimony was expected, and Dr. Sullivan's analysis confirmed the expectation: it is probably present to an injurious extent in type-foundries. Stable air was shown to contain cuticle-scales and hair; and hairdressers' establishments had a similar atmosphere. Some appalling revelations of the contents of dissecting-room air were made. Smoke being microscopically examined, the tobacco-smoker's air was shown to contain globules of nicotine, a poison. The air inhaled by tea-tasters was discovered to contain tea, sprinkled with fibres, tissue, and drops of a powerful narcotic oil.

He concluded by stating his conclusions arrived at with regard to lung-functions and contagion.

CORRESPONDENCE.

TETRABROMIDE OF CARBON.

To the Editor of the Chemical News.

SIR,—I am very sorry to trespass again upon your valuable space, but a letter from "The Reporter" in the *CHEMICAL NEWS* (vol. xxi., p. 273), seems to call for some remark.

In our paper communicated to the Chemical Society on May 5th, the following passage occurs "The bromination

of the bisulphide may, however, be effected by two different methods: by submitting it to the action of bromine in the presence either of bromide of iodine or of antimony terbromide." Any chemist can perceive the great difference between this and the official Reporter's account published in the *CHEMICAL NEWS* (vol. xxi., p. 223).—I am, &c.,

CHARLES E. GROVES.

17, Rodney Street, Pentonville.

[The report should have read:—"This combination is obtained—1. by heating bisulphide of carbon with bromine and bromide of iodine &c." The omission of the word "bromine" was an oversight.—*Ed. C.N.*]

LIEBIG'S EXTRACT—BOILING WATER.

To the Editor of the Chemical News.

SIR,—I forward some observations on Liebig's extract, derived from my own experience on a walking journey; also the results of my experiments on boiling water with the minimum of fuel.—I am, &c.,

W. T. SUFFOLK.

I became acquainted with Liebig's extract of meat during an illness last summer, when it was prescribed as an article of diet. I had been suffering from indigestion, and could not help noticing the ease with which it was assimilated and its speedy restorative action. Having experienced so great benefit from its use, I resolved to give it a trial during a long pedestrian excursion, and endeavour to test its value as food.

The action of the extract is very marked when used as a remedy for the exhaustion so frequently attending long and fatiguing walks, closely resembling in its effect the well-known restorative, tea and brandy, but it is much more permanent, acting not only as a stimulant, but also as nutritive matter.

The extract cannot well be used by itself as a substitute for ordinary food, but when accompanied by a quantity of less nutritious and digestible matter greatly augments its dietetic value. With Liebig's extract, bread or biscuit, and, if possible, hard-boiled eggs, the pedestrian will be provided for nearly every emergency. For the sake of variety of flavour, pepper, salt, curry powder, or other condiments may be used.

I prefer, when possible, to use the extract in the usual way—dissolved in hot water as soup,—but where hot water cannot be procured, it may be thinly spread upon bread or biscuit and eaten with equal effect. In either way it gives strength almost immediately, and stands very much in the same relation to ordinary food that petroleum does to coal as a steam-producing fuel, enabling power to be speedily obtained.

It must, however, be borne in mind that stimulating food can only be employed as an auxiliary, and not as a substitute for proper rest, the only true restorative. In long pedestrian journeys everything depends upon intervals of rest and proper food, if the exertion is to be continued for many days in succession.

Spirit of any kind should always be used cautiously; as its stimulating power is at the best of short duration nothing is added to actual bodily strength. It is sometimes of value in cases of difficult breathing, caused by steep ascents, a teaspoonful of strong brandy or whisky generally giving instant relief; also in the nervous giddiness which occasionally affects travellers, especially solitary ones, when walking on narrow elevated paths. This may seem somewhat like acquiring "Dutch courage," but nevertheless the discreet use of spirit in such cases is not to be undervalued.

For the purpose of boiling water *en route*, I employ an "Etna" of French construction, made of very thin copper, electro-plated, and weighing, with a store of 6 ozs. of spirit, 1½ lbs.

The time occupied in boiling half a pint of water is

from seven to ten minutes, and the consumption of spirit about two fluid drachms. The apparatus requires a perfectly calm atmosphere for its proper action; this may be secured by building a small cromlech of flat stones, which are always at hand in hilly countries, and with the help of a large handkerchief as a further protection against the wind, no difficulty will be found in securing efficient performance; other contrivances will suggest themselves where stones are not procurable.

Although it would seem that alcohol is consumed to a disadvantage without a wick, yet practically the "Etna" boils water with a smaller consumption of spirit than any contrivance I have yet tried. My best lamp, an argand, requiring at least half an ounce to do the same work as the Etna. The Russian blast lamp is still more wasteful, consuming nearly 2 ounces.

I attribute the superior economy of the Etna to the low temperature of the wickless flame and the manner in which the boiler is wrapped in the fire, no more heat being supplied than can be taken up by so bad a conductor as water. The defect of all lamps giving an intense flame being that heat is wasted by being supplied too quickly, so that the apparently feeble fire in the gutter of the Etna is more efficient than the heat of powerful lamps, as well as more economical; the latter quality is very important to the pedestrian, to whom every ounce of weight is a consideration.

OZONE AND SULPHUROUS ACID.

To the Editor of the Chemical News.

SIR,—I am not aware that the resemblance between these substances has been noticed, though, that O_3 and SO_2 are molecules containing the same number of like atoms similarly condensed, must be readily apparent, as also that the series

might be continued to include OO_2 , just as naturally as the series

includes as its last term OH_2 .

That the argument may not, however, rest solely upon considerations of atoms, volumes, and family analogies, which might be deemed by some persons fanciful and inconclusive, I rapidly parallel a few physical or chemical correspondences:—

OO_2 .
A (1). Odorous, dense, colourless gas.

A (2). Bleaches, disinfects, deodorises.

A (3). Tarnishes moist metals, *e.g.*, Fe.

A (4). Absorbed totally by turps.

A (5). Whitens lead-paper previously blackened by H_2S .

A (6). Absorbed by solution of KI, rendering latter yellow by disengagement of free I.

A (7). Antozone (its complementary molecule), according to M. Soret, moderately soluble in water,

$O_3 + 3H_2O = 3H_2O_2$ yielding a liquid (oxygenated water) partaking properties of gas O_3 .

A (8). Solution reduces Ag from its ammonio-nitrate.

SO_2 .
B (1). Pungent, dense, colourless gas.

B (2). Bleaches, disinfects, deodorises.

B (3). Corrodes moist metals, *e.g.*, Fe.

B (4). Absorbed partially by turps.

B (5). Whitens lead-paper previously blackened by H_2S .

B (6). Absorbed by solution of KI, rendering latter yellow.

B (7). Very soluble in water,

$SO_2 + H_2O = H_2SO_3$ yielding a liquid partaking properties of gas SO_2 .

B (8). Solution reduces Ag from its nitrate on heating.

A (9). Equilibrium of molecule, very unstable, *e.g.*, H_2O_2 converted to $2H_2O$ by nascent H, on one hand, and to $H_2O + O_2$ by addition of MnO_2 .

A (10).
 $3H_2S + O_3 = 3H_2O + S_3$.

B (9). Equilibrium of molecule somewhat unstable, *e.g.*, SO_2 converted to H_2S by nascent H, on one hand, and to H_2SO_4 on other by addition of MnO_2 .

B (10).
 $2H_2S + SO_2 = 2H_2O + S_3$.

These are almost as many concurrences as could be expected in the first two members of any homogeneous series, and are more striking than those of H_2S and H_2O , the first two terms of the series before quoted by way of comparison.

But to the whole of these observations I anticipate the objection, "Impossible! SO_2 is universally recognised as a reducer, O_3 as an oxidiser. You assimilate things of diametrically opposite tendencies, *e.g.*, O_3 blues iodised starch paper, SO_2 removes the blue."

To this, if the above instances of chemical resemblances be not sufficient answer, I ask, in reply, "Who shall, after Brodie's experiments on the peroxides, say what is an oxidiser? Why, oxygenated-water itself reduces MnO_2 and AgO ! Why, in 10 (B), SO_2 is an oxidiser, not a reducer!"

Suffer me, then, to surmise that possibly the advance of chemical discovery respecting the allotropic conditions of oxygen may hereafter confirm that ozone belongs to the SO_2 type. This once admitted many other and important deductions must follow.

B. W. GIBSON, B.Sc.

Eaton Square, June 18, 1870.

MISCELLANEOUS.

New Work on Quantitative Analysis.—Professor H. Storer, the talented Professor of Chemistry at the Institute of Technology, Massachusetts, is engaged on a work on Quantitative Analysis, the first part of which will be ready in August. It is arranged in dictionary form, and will be one of the most complete and valuable works extant on analysis. The first sheet, which is now before us, treats of the Quantitative Estimation of Acetic Acid, Acetate of Aluminium, Acetate of Barium, Acetate of Iron, Acetate of Lead, Acetate of Sodium (or of Potassium), Acetate of Uranium, Aconitin, Albumin, Alcohol, together with Acidimetry and Alcoholometry. If all the subjects are treated as fully as those in the first sheet, as we have no doubt they will be, the work will be welcomed by all chemists.

British Association for the Advancement of Science (Fortieth Meeting).—The Liverpool Meeting of the British Association for the Advancement of Science will commence on Wednesday, September 14th, under the presidency of Professor Huxley, F.R.S., F.G.S., &c. The facilities for communication with Scotland, Ireland, and America, as well as all parts of England, render it probable that this meeting will be very numerously attended; and it is the earnest wish of the local authorities, the representatives of the various scientific bodies, as well as of all those officially connected with the Association, that the members and associates should receive a cordial welcome, and that everything possible should be done to make the visit agreeable and instructive. Liverpool enjoys special advantages in its power of affording the various sections suitable accommodation within a limited area. There is much connected with the trade of Liverpool which cannot fail to be interesting to strangers. The river Mersey, with its line of docks, five miles in length; the great works at Birkenhead; the large warehouses, fitted with the latest mechanical appliances; the quay sides, covered with the various produce of all climes; and the numerous charitable institutions on the river, offer a class of attractions almost peculiar to Liverpool;—while

its shipbuilding yards, foundries, chemical, and various other works on an extensive scale, and its vicinity to the mining and manufacturing districts, enable it to meet the tastes of all classes of scientific men. The proximity of Chester and the coast of North Wales places many interesting spots within easy reach, and excursions will be planned, affording the members and associates an opportunity of visiting such as they may select. Arrangements have been made with the Railway, Ocean, and Coasting Steam Ship Companies for the conveyance of members to and from Liverpool at a reduced rate. The proprietors of the principal hotels have submitted a moderate tariff of charges, not exceeding their usual terms, and numerous offers of private hospitality have been placed at the disposal of the local officials. There is a foreigners' club, and there are a large number of foreign gentlemen, engaged in business, who will assist in providing for the comfort of those continental visitors who may attend. Those who require information and assistance in the way of providing lodgings, or other accommodation, are requested to communicate with the honorary local secretaries, Messrs. Wm. Banister, R. Harrison, H. H. Higgins, and A. Hume, at the Municipal Offices, Dale Street, Liverpool.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, June 13, 1870.

Omitting memoirs, papers, and communications relating to other departments of science, this number contains the following original matter on physico-chemical and collateral sciences:—

Specific Heat of Mixtures of Alcohol and Water.—Drs. Jamin and Amaury.—The authors, after briefly alluding to a former memoir on this subject, now proceed to give, in a lengthy memoir, a description of a series of experiments based upon the employment of a general algebraic formula, which, in fact, appears to be applicable not only to mixtures of water and alcohol, but also to various other liquids for the purpose of estimating the specific heat of mixtures of the same and of water. The paper is chiefly an algebraico-physical essay.

Physical Phenomena Observed during the Bursting of Hollow Cast-Iron Projectiles (Bomb-Shells, &c.), brought about by the Freezing of Water.—Dr. Ch. Martins and G. Chancel.—The authors reply to the observations and remarks made to their first communication on this subject by General Morin and other savants, and point out that the object they had in view while making these experiments, was to learn under what conditions, and with what phenomena, hollow cast-iron vessels (projectiles being most available for such purpose) will burst; moreover, the decrease of bulk of the bomb-shell, brought on by the cold, is only 1.33 c.c., a quantity too small to affect the experiment. The authors agree, however, with the General, that there is a very essential difference between the action of gunpowder and of freezing, although the ultimate effect is the same—viz., bursting of the projectile.

Cause of the "Rochage" of the Carburets of Iron, and on the Sparks Produced by these Metals.—H. Caron.—The author understands, by *rochage*, a peculiar production of sparks, best seen when molten cast-iron is run off from the blast furnace into moulds. In this lengthy paper, the author describes a series of experiments undertaken with the view to prove that, since steel and cast-iron, when molten in an atmosphere of hydrogen or oxide of carbon, never emit sparks, the production of the latter cannot be due to an evolution of reducing gas absorbed during the fusion, but is due, according to the author, to the formation of oxide of iron at the moment the molten metal comes in contact with air. When iron is kept fused in an atmosphere of hydrogen, its sp. gr. is increased from 7.84 to 7.88, while the metal becomes as soft and malleable as copper. When cast-iron is kept fused for a long time in a crucible, it absorbs oxygen, becomes lamellar, and, on cooling, contracts so suddenly as often to leave the inside of the mass hollow.

Mechanical Equivalent of Heat.—J. Violle.

Electrolysis of Air, or Oxygen, as a means of Producing Ozone.—A. Houzeau. The author of this paper summarises, in thirteen corollaries, all facts relating to, and brought out by, a series of no less than 400 experiments made by him on this subject. The author also states that he has contrived what he calls an *ozoniseur*, a machine to convert, instantaneously, any desired quantity of air or oxygen into ozone.

Researches on Platinum.—P. Schützenberger.—The author states that the chloro-platinite of carbonyl, COPtCl_2 , and the chloro-platinite of dicarbonyl, $\text{C}_2\text{O}_2\text{PtCl}_2$, may be viewed as being the chlorides of two diatomic compounds—viz., platoso-carbonyl, (COPt), and platoso-dicarbonyl—

And, in order to prove the correctness of this view, describes at length, in this paper, the action of ammonia, of ether, of protochloride of phosphorus, and other reagents, upon the compounds alluded to, and upon the chlorides of platinum.

Tribromhydrine.—L. Henry.—The main object of this very exhaustive and lengthy memoir is to prove the absolute identity of tribromhydrine and tribromide of allyl.

Action of Ammonia upon Lecithine.—M. Gobley.—By the action of ammonia upon this substance, the author has succeeded in producing neurine, margaramide, and adipoglyceric acid. Samples of these substances were exhibited at this meeting of the Academy.

Hailstorm near Alais on May 29th last.—E. Bourgoigne.—In a letter to M. Dumas, the author relates the particulars of a fearful hailstorm which has taken place in and around Alais (Département du Gard) on the above-named day, and which caused an immense destruction of property of various description, utterly destroying all crops, killing lambs, and covering the roads with hail to a depth of 30 centimetres (11.81 English inches). Most of the olive and nut-trees were decorticated, and a very old olive-tree cut off at the roots, and carried to a distance of 30 metres by the violent wind prevailing during the storm, the like of which has never been witnessed there before, being far more violent than that which took place in 1830 in the same locality.

The Bouma das Morts, near Alais.—The scientific committee occupied with the investigation of this grotto write to the Academy to say that they have discovered that originally this grotto was a lead mine, worked for the extraction of the ore of that metal, at a so remote period that it is at present difficult to form any opinion thereon; and it appears that, afterwards, the cavity has been either the habitation or the sepulchre of an extinct human race, the remains of which are now being fully explored.

Lowering the Temperature of Water.—A. Toselli.—The eminent Permanent Secretary of this Institute, M. Dumas, says—The author asserts that he has succeeded in lowering the temperature of water 13° C., by immersing, in that fluid, a tube spirally wound and turned round its axis. The author gives a complete drawing of that tube, but does not state how the experiment is to be made, nor what means employed to bring about the very desirable cooling, desirable especially during hot summer days.

The American Journal of Science and Arts, No. 147, May, 1870.

Omitting the titles, of the original papers and memoirs contained in this number and intended for full publication in our paper, we abstract and quote the following original papers relating to chemistry and collateral sciences:—

Method of Producing, by the Electric Spark, Figures similar to those of Lichtenberg.—E. W. Blake, jun.—The author reviews the history of electricity and the production of the figures alluded to, and then states—The method consists in throwing the discharge upon the surface of a fusible non-conducting body. If the body be near its fusing-point, the figure appears at once; if cold, a latent image exists, which may be developed by heat. The non-conducting surface is prepared by coating a plate of metal with an even film of pitch. Pieces of sheet tin, 3 inches square, coated with films of pitch of a thickness varying between 0.01 and 0.02 inch, were used; the pitch was the ordinary article of commerce, freed from sand, &c., by being melted and strained through a muslin bag. Shellac, resin, Burgundy pitch, bees'-wax, and Canada balsam were, in turn, tried as substitutes for pitch, but with unsatisfactory results. The author then describes (illustrating that description by woodcuts) his electric apparatus, and gives cuts, also, of the figures (Lichtenberg) as produced by frictional electricity and the induction coil.

Magnesium and Electric Lights as applied to Photo-Micrography.—J. J. Woodward.—A lengthy paper, illustrated by several engravings.

Mechanical Finger for the Microscope.—J. H. B. L.—With woodcuts.

Combinations of Silicon with Alcoholic Radicals.—C. Friedel and J. M. Crafts.—This lengthy memoir is divided into the following sections:—Silicic ethide; action of bromine on silicic ethide; the oxide of silicic tri-ethide; action of chlorine on silicic ethide; the acetic ether and the alcohol of silicic ethide; oxidation of silicic ethide; silicic methide; silicic ethide and methide.

Description and Analysis of the Franklin County Meteoric Iron; with Remarks on the Presence of Copper and Nickel in Meteoric Irons, the Method of Analysing the same, and the probability of the Lead in the Tarapaca Iron having been

originally foreign to that mass. J. Lawrence Smith.—This rather lengthy paper treats, in its first section, of the Franklin County meteoric iron (sp. gr. 7.692); its weight was 24 lbs. Composition, in 100 parts:—Iron, 90.58; nickel, 8.53; cobalt, 0.36; copper, minute quantity; phosphorus, 0.05.

Examination of a New and Extraordinary Gas-Well in the State of New York. H. Wurtz.—This paper is chiefly of local importance; but the following brief scraps have a general bearing. It appears, in the first place, that some four years ago, the owner of a piece of ground in the township of West, Bloomfield County, Ontario, while boring for petroleum, struck, at about 500 feet below the surface, a cavity from which a copious stream of gas commenced blowing off at the rate of 400,000 cubic feet per day. The bore-hole is tubed down, and 5 inches in diameter; and the issuing gas, when burning, gives, in a still atmosphere, a flame 30 feet high. This phenomenon has now continued for fully four years. The gas consists, per cent., of—Marsh gas, 82.41; carbonic acid, 10.11; nitrogen, 4.31; oxygen 0.23; illuminating hydrocarbons, 2.941—sp. gr. 0.593.

Certain Double Sulphates of the Cerium Group.—C. H. Wing, New Aspirator.—J. C. Draper.—Illustrated with a woodcut. The principle is that of the Giffard's injector.

Action of Sunlight on Sulphurous Acid.—O. Loew.—The author found that, when aqueous sulphurous acid was exposed in sealed tubes to the action of sunlight, it was gradually reduced to sulphur, but the oxygen was not liberated, another part of the acid having been oxidised by it to sulphuric acid.

Simple Method of Avoiding Observations of Temperature and Pressure in Gas Analyses, and on the Application of Sprengel's Mercurial Pump in Analysis.—W. Gibbs.—Illustrated with a series of algebraic formulæ and woodcuts.

Peculiar form of the Discharge between the Poles of the Electric Machine.—A. W. Wright.—With diagrams.

Movement of the Dome of the Capitol at Washington during the Gale of December 10–12, 1869.—T. Walter.—Although the contents of this paper do not strictly belong to the subjects usually treated of in our periodical, we cannot refrain noticing the curious effects here recorded. The author had constructed a very sensitive apparatus to test the effect of the expansion of the Dome (an iron structure, 137 feet in diameter and 200 feet high) by the sun's rays; it happened, however, that the wind, and not the sun, made use of the author's preparations, and recorded its vagaries through the agency of the vast mass of the dome. One would think such a mass immovable against any action of wind; but this is not so. The author gives a diagram, proving, what a gusty day was capable of effecting in giving motion to the mass. It is a well-known fact, that tall chimney stalks and high church steeples, shot-towers, and the like, move about in rough weather, as also, perceptibly, do the high towers of Antwerp and Utrecht, though very massive buildings; but movements in a dome such as that alluded to could hardly have been reasonably expected.

Zeitschrift für Chemie von Beilstein, No. 9, 1870.

This number contains the following original papers and memoirs:—

Action of Nitric Acid upon Azotoluide.—V. Petrieff.—When nitric acid (sp. gr. 1.5) is added to azotoluide, and care taken to cool the mixture, mononitro-azotoluide is formed which is almost entirely soluble in alcohol. On evaporating this solution, two substances are obtained, both composed of $C_{11}H_{10}NO_2N_2$: one of these bodies, a red substance, fuses at 67°; the other, yellow, fuses at 63°. When, however, crystals of azotoluide are added to strong nitric acid, without cooling, two other substances are formed—viz., trinitro-azotoluide, soluble in boiling alcohol, difficultly soluble in ether, fusing at 185°, formula $C_{11}H_7(NO_2)_3N_2$; and a body insoluble in alcohol, but soluble in benzol and nitric acid, fusing at 207°, exploding violently when heated to a higher temperature; formula, $C_{11}H_7(NO_2)_3N_2O$. The author has also tried to obtain these substances by the action of nitric acid upon azobenzide; but this reaction did not lead to the desired results, azoxybenzide being formed. The action of pentachloride of phosphorus is as follows:—

A Body Homologous with Benzidine.—W. Petrieff.—Hydrazotoluide is converted, by the cautious addition of sulphuric or chlorhydric acids, into a crystalline body homologous with benzidine, fusing at 128°, and readily soluble in boiling water, alcohol, and ether. This base yields, with sulphuric acid, two different salts, one of which is soluble in boiling water and in alcohol, the other insoluble therein; the formula of the latter is $C_{11}H_{12}N_4 \cdot 2H_2SO_4$. The author observes that he obtained this body only from hydrazotoluide, prepared, by means of sodium amalgam, from hydrazotoluide.

Action of Hydrobromic Acid upon Azoxybenzide.—R. Sendzink.—When hydrobromic acid acts upon azoxybenzide, a substance is formed which proved to be bibromaniline—

This reaction, however, only takes place when a large excess of hydrobromic acid is taken; with a small quantity of the latter, an oily substance is obtained, and very little bibromaniline. Hydriodic acid converts azoxybenzide very readily into benzidine.

Researches on the Allyl Group.—B. Tollens.—The author, referring, first, to some of his former experiments on this subject, states that allyl-alcohol, obtained by him, does not yield, when treated with substances which give off hydrogen, either propylic or isopropylic alcohol. The preparation of allyl-alcohol from glycerine and oxalic

acid, is rendered difficult, by reason of a small quantity of alkali, almost always present in oxalic acid, and very difficultly removable from it. The author, therefore, adds from 4 to 1 per cent of hydrochloric acid, whereby this objection is obviated. Sulphuric acid may be used, but excess of either should be avoided, especially since even a slight excess of chlorhydric acid causes, at about 200° (the most suitable temperature for the reaction), the formation of mono-allyline—

a liquid boiling at 240°, but then, also, partly decomposed.

Some Additional Observations on the Formation of Ozone in a Flame.—O. Loew.—This paper is written as a reply to some remarks published by Dr. Büttger on the author's observations on this subject, wherein the former chemist says that peroxide of hydrogen and carbonate of ammonia are formed in the manner described by the author (see CHEMICAL NEWS, vol. xxi, p. 107). The author now states that, by using a pair of bellows and a large Bunsen gas burner, he has filled, in a short time, a large room with the peculiar odour due to ozone, while delicate tests failed to detect any peroxide of hydrogen or carbonate of ammonia.

Revue Hebdomadaire de Chimie, June 2, 1870.

Analysis of Three Sorts of Corn cultivated near Saulsaie (Département du Rhône).—Dr. J. Roussille.—This grain (wheat) had been grown experimentally for the purpose of trying a peculiar kind of soil containing no less than 88.9 per cent of silica insoluble in hydrochloric acid. The sorts of corn are termed *bleu, rouge, and fern*, and were found to contain, in 100 parts, respectively—Water, 14.2, 14.10, 15.32; organic matters, 84.8, 84.22, 82.78; mineral matter, 1.72, 1.68, 1.9. The yield per hectare of each was, in kilos, of the thrashed-out grain, 2576, 1429, and 1956. The soil alluded to contains 0.060 per cent of phosphoric acid and 2.17 per cent of organic matter.

Jahrbuch der Kaiserlich-Königlichen Geologischen Reichsanstalt, No. 1, 1870.

This periodical appears only quarterly, and is, moreover, rarely published with great accuracy as to date of publication, it being an official, not a commercial undertaking.

This number contains the following original papers relating to physico-chemical and collateral sciences:—

The Town of Oldenburg and its Environs in relation to Water Supply.—H. Wolf.—The town alluded to is in Hungary. The lengthy memoir deserves special notice as an excellent contribution to economic-geological surveys of this description. The paper is illustrated with maps and engravings.

Report on the Production and Circulation of the Mineral Fuels, and the Localities where these are Found and Wrought in the Austro-Hungarian Monarchy.—F. Fetterle.

The Kainite from Kalusz, in Galicia.—Karl Ritter von Hauer.—The celebrated author of this lengthy memoir states that the kainite found in large quantity at the locality alluded to contains, on an average, in 100 parts—Sulphuric acid, 20.46; chlorine, 28.01; magnesia, 10.16; potassium, 16.38; sodium, 7.97; calcium and protoxide of iron, a trace; water, 14.36; clay, 3.41. Formula, $KCl + 2(MgO \cdot SO_2) + 6H_2O$. The kainite here alluded to agrees very closely in composition with that found near Stassfurth. The author enters, at great length, into details about the manufacture of salts of potassa from this mineral.

Revue des Cours Scientifiques de la France et de l'Etranger, June 11, 1870.

This number does not contain any papers directly relating to chemistry; but it contains a lengthy and very clearly-written paper, illustrated by several woodcuts, on the—

Use of Steam-Backing in Locomotive Engines.—M. Le Châtelier.

And a lengthy lecture by the celebrated Heidelberg physiologist, Dr. Helmholz, on the—

Physiological Action of Electric Currents of Short Duration in the Interior of Conducting Bodies.

Les Mondes, June 9, 1870.

The Arènes at Paris.—Rev. Michon.—A lengthy paper illustrated with several woodcuts, and describing the various objects of scientific and historical interest found in this very ancient building, which, for some centuries, has been covered over by the mould and rubbish of a city of later date.

Experiments on the Physiological and Therapeutical Properties of Phosphate of Lime.—Dr. R. Dusart.—The chief point of interest in this paper is that phosphate of lime, in some form or other, is absolutely required for the proper performance of the functions of nutrition, since it causes the albumenoid substances to form cells and tissues. The author speaks of a lacto-phosphate of lime as a therapeutic agent, but does not specify what that substance is; it may be a double salt of lactic and phosphoric acid with lime.

Distances at which Sound can be Heard.—Rev. F. Moigno.—The fog-horn established at Foucher can be heard, in calm weather,

at a distance of 28 kilometres; during storms, at a distance of from 9 to 15 kilometres; and with wind blowing in the direction wherein the sound is sent (seaward), 46 kilometres. The cannonade at the battle of Waterloo (June 18, 1815) was heard at Creil (France), 200 kilometres distant therefrom; and the cannonade at the battle of March 30th, 1814 (near Paris), was heard distinctly at Casson, between Lisieux and Caen, at 176 kilometres' distance, in each case as the crow flies.

Conversion of an Ordinary Electric Machine into a Holtz's Machine.—Rev. Dr. Laborde.—A lengthy paper wherein the author points out how the desired object can be obtained, temporarily, for the purpose of lecture-room experiments.

Cosmos, June 11, 1870.

Effects of Cold upon Plants.—Dr. Zurcher, writing from Toulon, states that on the night from the 3rd to 4th of January last, the thermometer in the public garden of the town alluded to marked -8° , and that a large quantity of snow covered the ground and the trees, among which a number of palm-trees, and even *Chamaecrops* and *Jubæa*, none of which, though exposed to this low temperature, suffered any damage. From observations made by the author and several other parties, it appears that, as regards the injury done to the plants by great cold, the effects thereof do not depend so much on the degree of cold, as on the calmness of the air (absence of wind) and absence of moisture.

Means of Detecting the Genuineness of Kirschwasser.—S. Meunier.—Place, in a test-tube, some powdered guaiacum-wood, and add to it some of the Kirschwasser to be examined. If the latter is really genuine, an indigo-blue colour will forthwith appear, and continue for about an hour; but, if the liquor has been prepared with essential oil of almonds, *Aqua laurocerasi*, or crushed cherry-stones macerated in alcohol, only a yellow tint will be produced. The rationale of this curious phenomenon is not explained, and will be the subject of further investigation. Kirschwasser contains, when genuine, hydrocyanic acid, hydride of benzoyl, and a peculiarly-flavoured essential oil not known in the isolated state.

Moniteur Scientifique, No. 324, June 15, 1870.

This number contains the following original papers and memoirs relating to physico-chemical and collateral sciences:—

Experiments on the Salts of Manganese.—Dr. A. Commaille.—The author describes at length the action of acids upon permanganate of potassa, aided, in some instances, by the reducing action of alcohol, ether, and electricity. The author observes, casually, that the salts of the protoxide of manganese are, when perfectly pure, quite colourless. The memoir is divided into the following sections:—Nitric acid and permanganate of potassa; sulphuric, hydrochloric, iodic, arsenious, oxalic, acetic, tartaric, citric, tannic, benzoic, and uric acids, respectively, with permanganate of potassa. The author found that, under the influence of the electric current and chlorhydric acid, hydrogen gas alone is given off from the permanganate; the same is observed, under similar conditions, with oxalic acid.

Palm Oils of Commerce.—P. Guyot.—Palm oil is obtained from the fruit of the *Avouira* or *Croco* palm-tree, growing on the coast, and also in the interior of the Guinea. It yields two kinds of oil—viz., a white-coloured, butter-like substance, extracted from the kernel of the fruit, and chiefly used by the natives as food; the point of fusion of this oil is stated to be rather high. The other kind is extracted from the fibrous sarcocarpium surrounding the fruit; at the prevailing temperature of its native country, this oil is fluid, but in Europe it has the consistency of butter; its colour is yellowish orange, and its smell is very much like that of violet flowers; it is insoluble in cold as well as boiling water, slightly soluble in alcohol, and very soluble in ether. The author gives, in a tabulated form, the results of the action of different reagents upon the oil alluded to, and some of the commercial varieties thereof, as imported from other countries where the oil is obtained either from the same or some other kind of palm-tree. The action of the reagents alluded to (sulphuric and nitric acids, ammonia, chloride of zinc, protochloride of tin, persulfate of mercury, and liver of sulphur) is not sufficiently characteristic to be specifically quoted here; and this is the less necessary, because, as the author also states, adulteration of these oils would not be practised in the country whence they are exported, and certainly not in Europe, unless it were done in a very wholesale manner, and with the application of very inferior fats. The complete solubility in ether is a sufficient test of purity; the colouring matter is readily destroyed when desired.

Extraction of Copper from its Ores.—MM. Tessié du Motay and Co.—The authors propose to apply their oxyhydrogen gas for the purpose of oxidising, from copper ores, the other metals they may contain, after such ores have been previously treated so as to be in the state of metallic silicates, as they call it.

Application of Phenic Acid for the purposes of Leather and Skin Manufacture.—E. L. C. Baudet.—The author describes, at great length and very exhaustively, all the operations whereby hides and skins are converted into what is generally called leather, and proposes the use of phenic acid as a preservative against various kinds of injury, as well as the ready-made materials are subjected to, from the forresses, both during and after their conversion from animal comes in no saleable commodities.

in an atmosphere of H_2 .—Cuttings among Rasp Hartshorn.—F. to 788, while the metal becomes 2 grms. of the material to be tested. When cast-iron is kept fused for a short time by means of a fine sieve; next, oxygen, becomes lamellar, and, on 4th for an hour with water, to collect often to leave the inside of the ma:

the insoluble residue on previously-counterpoised filters, to wash well with boiling-hot water, and to weigh after drying. If the loss in weight is below 6 per cent, the conclusion, says the author, may safely be that the sample in question does not contain even a trace of genuine hartshorn; if the loss by weight is above 6 per cent, the number, 6, should be deducted from the quantity found, which should be designated as n ; and the proportion, supposing 10 per cent loss to have been found, will stand— $8:100=4:x=50$ per cent of genuine hartshorn. Since, however, the use of hartshorn, as well as of such preparations as the once renowned *Decoctum album Sydenhami*, are now altogether forgotten, and superseded by more simple substances, this test has only a scientific interest, as indicating in genuine hartshorn a far larger amount of matter soluble in water than is present in bones.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 3, 1870.

This number contains the following original papers relating to physico-chemical sciences:—

Meteorite from Saint-Denis-Westrem, near Ghent.—S. Meunier.—This stone, weighing 720 grms., which fell from the sky on the 7th of June, 1855, the fall being accompanied by a loud detonation and strong emission of light, belongs, according to the author, to what he terms *lucite*, a white-coloured, fine-grained, harshly-feeling very crystalline substance (sp. gr., 3.43) consisting for 88.9 per cent of a lithoid matter, made up of silica, magnesia, oxides of iron, alumina, soda, and potassa, with traces of lime and oxide of chromium. Fully 65 per cent of this quantity is soluble in chlorhydric acid. By means of the magnet, about 8 per cent of metal, chiefly iron, is separated. The paper contains an exhaustive discussion on the origin of meteorites; and the author states that our moon is gradually tending more and more to become broken up into smaller spheroids, some of which may reach our globe as meteoric stones at a future day.

Discovery of a Layer of Native Phosphate of Lime under the City of Louvain (Louvain), Belgium.—G. Lambert.—It appears that the municipal government of the city alluded to have, for some purpose or other (not specified), been making borings deep into the soil in a central part of that place. Among the minerals obtained are—At a depth of 110 metres from the surface, a layer of a material containing—water driven off at 100° , 1.28 per cent; water driven off at red-heat, after drying at 100° , 6.44 per cent; insoluble in chlorhydric acid, 16.42 per cent; anhydrous phosphoric acid, 29.90 per cent. This material contains, therefore, about 62 per cent of tribasic phosphate of lime.

NOTES AND QUERIES.

Bromine.—Can you, or any of your readers, give me a thoroughly-accurate process for the separation of bromine from bromic acid, where the two exist together as a bromide and bromate of an alkali.

—J. H. WATSON.

Phosphate of Ammonia.—(Reply to "J. W. M.")—You will find, in any of the larger works treating on chemistry, what you require. Consult the excellent work of Dr. W. A. Miller, or Watts's "Dictionary," and the works of the late Dr. Brande, &c., all of which you can inspect at the Library of the Commissioners of Patents.

Persulphide of Hydrogen.—I should feel obliged if you can inform me whether the actual composition of persulphide of hydrogen has ever been demonstrated analytically, as I am endeavouring to attain this myself.—W. B. G.

Method for the Removal of Stains of Iron Mould from Fabrics. The removal of these stains is a matter of some difficulty if they have remained on a fabric for some time. The usual substances employed for this purpose (oxalic acid or quodroxalate of potassium) require placing, in concentrated solution, in contact with the material for a considerable time, thereby materially weakening and rotting the fibre. The following method is free from this objection, and will remove stains of long standing almost immediately:—Wet the mark with yellow sulphide of ammonium, by which it will be immediately blackened, and allow it a minute or so to penetrate; then wash out the excess of sulphide, and treat the black spot with cold dilute chlorhydric acid, by which it is immediately removed. Finally, wash well with water.—W. B. G.

TO CORRESPONDENTS.

J. R.—The method given in Fresenius may be relied on.

W. N. (Huddersfield).—There is no objection to the use of hydrochloric acid instead of sulphuric in the preparation of CO_2 , provided the gas is washed with carbonate of soda solution.

F. C. S.—Your letter has been referred to the reporter.

B. W. Gibbons.—Thanks for your paper; it shall be inserted in an early issue.

James R. Gregory.—We have received your catalogue of minerals, &c.; it seems to be very complete, and the prices being affixed makes it valuable to all mineralogists.

J. Pattison.—A work by the Editor, embracing both the subjects you name, is in the press.

Chrome Colour.—There is a letter for this correspondent at our office.

J. W. M.—Send your address to our publisher.

THE ELECTRO-DEPOSITION OF COPPER AND BRASS UPON IRON.

By W. H. WALENN, F.C.S.

THE early attempts to electro-coat iron with copper were unsuccessful, in consequence of all acid and neutral solutions of copper acting upon articles of iron immersed therein. This difficulty was overcome soon after Elkington's electro-silvering process was made known (in 1840) by using alkaline solutions. Alkaline sulphites, hyposulphites, cyanides, ferrocyanides, and other salts, also a mixture of these, have been used, the only salts that stood the test of time, as menstrua or solvents in which to dissolve the copper, being potassic cyanide and some combinations of this remarkable salt with ammonia and ammoniacal salts. Practical working, however, soon showed that one difficulty was overcome, but others of an important nature were introduced.

The small solubility of copper compounds in potassic cyanide, the weak action of the solution upon the anode, the small electrical conductivity of this class of metallic solutions, and the strong disposition to evolve hydrogen gas during deposition are the most important of the drawbacks to the successful working of alkaline copper solutions to coat iron. All these peculiarities have been lessened or overcome, to a certain extent, for more than fifteen years past, excepting the last—the evolution of hydrogen. The price at which they have been overcome, however, is almost suicidal to success. The action of heat upon the solution is not only to increase its solvent power, and its electrical conductivity, but also to somewhat increase the expense and trouble of working the process. An increase in the number of cells of which the battery is composed, or of the electro-motive force, acts in a similar manner to heat in regard to the solvent power and electrical conductivity of the solution this, however, not only largely increases the expense, but tends to overcharge the solution and to produce a brittle deposit that is also spongy, the sponginess or initiative tree-like formation arising from the evolution of hydrogen gas during deposition. Nevertheless, by the combination of these two agents, heat and increased electro-motive power, the solution of cupric cyanide in potassic cyanide is enabled to deposit copper upon iron in a form which is barely marketable, but which is obliged to be varnished, and then has scarcely the metallic appearance of a good application of bronze powder.

The evolution of hydrogen gas during deposition is not a difficulty that the early workers in electro-metallurgy would have anticipated, for (with the exception of the cyanide silver solutions) it did not occur to them to employ other salts than those of the metal to be deposited. When, however, the salts of the alkaline metals are employed, instead of the simple acids or hydric salts, as solvents for the metals to be eliminated from a given solu-

tion by means of electrolysis, the disposition of the metal of the alkali to go to the negative pole along with the metal dissolved in it, renders the alkaline solutions prone to evolve hydrogen from the decomposed water of the solution.

The prevention of the evolution of hydrogen gas from the cathode lessens the amount of electro-motive force required and tends to the formation of a solid deposit, and one that does not consist merely of a very fine network but is continuous over the whole surface covered, it also tends to preserve the solution in the normal condition and to improve the quality of the metal. A remark from Dr. Miller, of King's College, to the writer, led to the discovery of a method of working without the evolution of hydrogen, and Dr. Frankland, of the Royal College of Chemistry, suggested to him (the writer) a means of carrying out that method which ultimately proved to be practical. This method, consists in supplying to the ordinary cyanide solution, or to a solution set forth in the Patent Specification No. 1540 (A.D. 1857), after the cyanide of copper is dissolved therein to the proper extent, the hydrated oxide of copper in a wet state, in small but sufficient quantity; as a means of adjustment and absolute prevention, the blue or purple ammoniuret of copper may be added.

When the cyanide of a fixed alkali and a salt of ammonia are mixed to form an electrolytic solvent solution, the resulting solution, with some exceptions, is found to have the remarkable property of dissolving a brass anode and of giving up the brass to a cathode (of cast- or wrought-iron for instance), in a tolerable reguline form, but with the copious evolution of hydrogen gas, the proportions of copper and zinc in the resulting alloy being dependent upon the heat of the solution and also influenced to some extent by the electro-motive force and by the relative size (area) of the anode and cathode.

Having tried many of these cyanogen compounds, the writer has found a mixture of potassic cyanide and ammoniac tartrate to give the best results and the least evolution of hydrogen; the addition of the wet hydrated oxides of the metals however, and especially of the ammoniuret of copper, entirely removes the tendency to the evolution of hydrogen. This combination of the solvent solution is treated of in Patent Specification No. 1540 (A.D. 1857), and the method of preventing the evolution of hydrogen in No. 3930 (A.D. 1868).

The action of the ammoniuret of copper in stopping the evolution of hydrogen, appears to be that of carrying oxygen to the cathode and thus enabling the hydrogen that would otherwise be evolved to unite with a sufficient proportion of oxygen to form water and to continue in solution. Upon this supposition, which is merely put forward as a suggestion, the ammoniuret of copper, as a whole, acts as a cation which, when it arrives at the cathode, is itself decomposed into metal, ammonium, and oxygen. According to this idea, the action which takes place may be stated by the formula

The best containing vessel for the copper or brass solution is a wrought-iron tank with a steam jacket and suitable fittings to it.

Articles of wrought-iron or steel are comparatively easy to electro-coat, care being taken to select good material, well puddled and free from scales or scoriae. The metal is taken from the workman's hands, if greasy, it is immersed for a few minutes in a boiling solution of caustic potash—one part of potash to ten parts of water—it is preferable, however, to keep grease away from articles that are to be electro-coated. It is then washed in running water and pickled in a bath containing one part by measure of oil of vitriol to twenty parts of water; this operation should not continue longer than is necessary to thoroughly free the iron from scale and to expose the absolute metallic surface. The heat at which the electro-depositing bath is used serves to finally cleanse the surface of the article (which should be washed before immersion therein), and promotes the adhesion of the deposit, it is well, therefore, to allow the articles that make up a charge for a bath to remain in a short time before completing the electrical circuit. At first the electric power should be small and it may be increased as the coating proceeds. The completed articles may be washed and well rubbed with hot mahogany sawdust, being allowed to remain therein for some hours.

Cast-iron is, perhaps, the most difficult substratum on which to build up an electro-deposit, but with care and by the selection of good material, the above-mentioned solutions furnish good results. The casting, trimmed, direct from the foundry, is pickled as above, washed, and well scrubbed with sand and water until its true metallic lustre appears in all its parts, it is then coated with copper in the alkaline copper bath, and when well covered, is removed to the electro-brassing bath, unless it is desired to copper it only. The operations require greater attention than those for wrought-iron and the final washing and drying should be thoroughly performed.

By this process, one Smee's cell may be used; six were originally requiring for electro-brassing. The cost has been found to be about 2s. 6d. per lb. of metal deposited. One ounce and a half of copper or brass per square foot will protect iron from rust.

A separate bath should be used for wrought and cast-iron, and even for different qualities of cast-iron. Order, cleanliness, and well-trained manipulation, in this department of applied chemistry, ensure success.

ON CYCLOPIC ACID,

A NEW FLUORESCENT SUBSTANCE EXTRACTED FROM THE
CYCLOPIA VOGELII.*

By ARTHUR H. CHURCH, M.A. Oxon, F.C.S.

ONE of the plants used by the African Boers, for tea, is the *Cyclopia Vogelii*. Endeavouring to extract theine from the dried leaves and flowers of this plant, I met with a substance apparently new to science, and possessing one remarkable property, that of a high degree of fluorescence. This character is best seen when a crystal or two of the new body is dropped into a solution of caustic soda and viewed in sunlight. An intense greenish yellow fluorescence is perceived at first, but disappears in the course of some hours.

I have named the new substance *cyclopic acid*. It is extracted by enclosing a pound or so of the dried leaves in a cloth, and immersing this for some days in water at about 30°–40° C., occasionally squeezing the cloth. A yellow powder gradually accumulates at the bottom of

the vessel of water, and should be dissolved in a mixture of ether, alcohol, and water, acidified with a drop of acetic acid. By two or three re-crystallisations from weak alcohol, the cyclopic acid is obtained pure. It contains only carbon, hydrogen, and oxygen; different samples gave closely accordant results on analysis—

Percentages of Carbon. Percentages of Hydrogen.

1.	53.43	..	..	..	5.78
2.	53.58	..	..	..	5.92
3.	53.40	..	..	..	5.13
4.	53.36	..	..	..	5.62

These numbers correspond pretty fairly with the formula $C_7H_8O_4$, which demands the following percentages:—

Carbon ..	%	..	..	..	53.84
Hydrogen ..	..	..	..	..	5.13
Oxygen ..	..	..	..	..	41.03

100.00

The formula, $C_7H_8O_4$, is rendered more probable by the result of neutralising cyclopic acid with a standard solution of ammonia. The formula indicated for the ammonium cyclopylate thus produced was $C_7H_6[NH_4]_2O_4$.

It is possible, however, that cyclopic acid contains more hydrogen than assumed above, in which case it would have the formula $C_{14}H_{18}O_8$, and its ammonium-salt be $C_{14}H_{14}(NH_4)_4O_8$.

ON THE

ESTIMATION OF FERROUS OXIDE, IN PRESENCE OF FERRIC OXIDE, IN SILICEOUS MINERALS.*

By CHARLES A. WILBUR and WALTER WHITTLESEY,
Students in the Massachusetts Institute of Technology.

At the suggestion of Prof. Storer, we have applied the observation of Avery† to the estimation of ferrous and ferric oxides in silicates. Avery found that silica and many silicates can be readily and completely dissolved by a mixture of some normal fluoride with almost any of the stronger acids, whether concentrated or dilute. He has promised to work out a method of determining all the constituents of a silicate in a single portion of the mineral after having dissolved it in a mixture of fluoride of barium, fluoride of lead, or the like, and nitric or chlorhydric acid.

We have confined ourselves to the estimation of the two oxides of iron, and have obtained satisfactory results so easily that we are led to hope and believe that our process will be found worthy of being generally adopted for the estimation of iron in silicates. Our method is as follows:—

A quantity of the finely-powdered silicate to be examined is weighed in a platinum crucible; as much, or rather more than as much, powdered fluor spar, free from iron (or of powdered cryolite), is poured into the crucible; the powders are thoroughly mixed by stirring with a glass rod; the rod is wiped clean upon a fresh portion of the powdered fluoride; and the latter is thrown upon the mixture in the crucible. Strong chlorhydric acid is then poured into the crucible, until the powder is thoroughly drenched and the crucible about two-thirds filled with the liquid. The crucible is set upon a water-bath, and heated until the iron has all dissolved; and the proportion of iron is finally determined by titrating with a standard solution of permanganate of potassium in the usual way. To protect the mineral from the air during the process of solution, the crucible must be kept full of some non-oxidising gas, which can be either carbonic acid or coal gas, as may happen to suit the convenience of the operator.

* Communicated by the Author. From the Report of the Chemical Department, Royal Agricultural College, Cirencester.

* Communicated through the kindness of Professor Storer.
† CHEMICAL NEWS, vol. xix., p. 270.

If carbonic acid be used, it is sufficient to cover the crucible with a bit of sheet-lead, perforated with two holes, through one of which is thrust a glass tube communicating with a gas-bottle in which the carbonic acid is generated, while the other serves as an outlet for the escape of carbonic acid and acid vapours. The crucible is, in this case, simply set upon an ordinary water-bath.

When coal-gas is used (and this agent is to be preferred on the whole), the apparatus may be arranged as follows:—Set the charged platinum crucible upon a glass or leaden tripod inside a wide beaker in the bottom of which there is about an inch of water. Invert a narrower beaker within the first, so that its mouth shall be sealed by the water and the crucible be enclosed in a transparent chamber. Coal-gas is led into this chamber through a bent glass tube, which passes down between the side of the upright and that of the inverted beaker, and delivers the gas near the top of the chamber. The surplus gas escapes through another tube, similarly bent, which starts from a point below the crucible, and is burned in the outer air.

To facilitate the passage of the glass tubes, the mouth of the inverted beaker may be made to rest upon three or four bits of stone or metal, or an orifice large enough to admit the tubes may be made upon the rim of the beaker.

During the process of solution, the upright beaker is kept immersed in water, at or near the temperature of boiling. In case the coal-gas should contain any sulphuretted hydrogen, it would be well to purify it by means of a potash-tube.

We have made numerous experiments to test the accuracy of the process and determine the time needful to effect the decomposition of an ordinary silicate. After we had found, by experiments, that simple mixtures of fluor spar and acid, which had been heated for an hour or two on the water-bath, exerted no decolourising action upon the permanganate, we proceeded to compare such mixtures with those which, besides the fluor spar and acid, contained weighed quantities of fine iron wire.

The results of this series of experiments are as follows:—

WHITTLESEY.

Wilbur.

The times of exposure to heat, upon the water-bath, of the mixtures of trap, acid, and fluor spar differed widely in the different cases.

We find that an hour and a half is ample for the solution of the iron in 0.5—1 gm. of the finely-powdered trap. Fifteen minutes, on the other hand, will suffice for the solution of 0.2 gm. of iron wire.

Instead of chlorhydric acid, sulphuric acid may be used to act upon the mixture of fluor spar and trap, as was done in the third and fourth experiments of the foregoing list, trap A. The sulphate of calcium formed in this case is objectionable, from its liability to envelope portions of the mineral and to protect the iron from being dissolved, rather than from any tendency to interfere with the actual titration.

Experiments were next made to determine whether the presence of sesquioxide of iron could interfere in any way with the estimation of the protoxide.

Commercial iron-alum, which of itself had no decolourising action on chameleon, had none after it had been heated with cryolite and chlorhydric acid. It was found, also, by acting upon weighed quantities of iron wire mixed with cryolite and iron-alum, that the iron can be estimated as well in the presence of the alum as in its absence, provided only that the metallic iron be dissolved in chlorhydric acid, with the necessary precautions to prevent oxidation, before adding the other ingredients of the mixture. If the iron wire, cryolite, and ferric alum were treated all at once with acid, some of the hydrogen generated by the solution of the metallic iron would reduce a part of the ferric salt; so that, in the final titration, more iron would be found than was introduced into the mixture in the form of wire.

To determine whether ferric oxide which had been strongly ignited could be dissolved by the process in question, one of us heated a couple of samples of the ignited oxide with fluor spar and chlorhydric acid during three or four hours, upon a water-bath. The dissolved iron was then reduced with zinc, and titrated with chameleon.

In the first experiment, the ferric oxide was in the form of small lumps; in the second it was powdered.

Weight of Fe ₂ O ₃ taken.	C.c. of chameleon used.	Per cent of Fe found.	Theory requires per cent.
0.1175 ..	6.37 ..	36.35 ..	70.00
0.1172 ..	12.10 ..	69.17 ..	70.00

It would appear that, if time enough be allowed, finely-powdered ferric oxide can be dissolved in this way, even after intense ignition.

To estimate ferric oxide in a silicate, a separate portion of the mineral may be treated with fluor spar and acid, the solution reduced by zinc in a small flask in the usual way, and the total amount of iron determined with chameleon. Or, if the mineral contains only a small proportion of ferric oxide, it will be sufficient to put a bit of zinc into the crucible with the mixture of mineral, fluor spar, and acid. The difference between the total iron and that determined as ferrous oxide is calculated as ferric oxide.

Two samples of trap A dissolved as above, with the addition of metallic zinc to the crucible, gave:—

	I.	II.

Boston, April, 1870.

ON SOME CIRCUMSTANCES WHICH FAVOUR THE SIMULTANEOUS PRECIPITATION OF ALUMINA AND MAGNESIA BY AMMONIA.

By LAURENCE F. J. WRINKLE,

Student in the Massachusetts Institute of Technology.

It was observed, long ago, by Abich (*Poggendorff's Annalen*, 1831, xxiii., 352), that the alumina precipitated by ammonia from mixed solutions of aluminum and magnesium salts, may hold considerable quantities of magnesia in insoluble combination; and that the whole of the alumina cannot be dissolved from such precipitates by boiling with caustic lye. The observation has been repeatedly verified, in the laboratory of the institute, by students who have endeavoured to analyse a mixture of Epsom salt and potash alum by the second of the methods laid down by Galloway, on page 86 of his "Manual of Qualitative Analysis," (London, 1864). It is there directed to dissolve, in the smallest possible quantity of boiling dilute chlorhydric acid, the precipitate produced by ammonia in the boiled filtrate from the precipitate viewed, by sulphuretted hydrogen, in the ordinary course of analysis, and to add to this acid solution, when cold, some hours. of soda or potash. The purpose of the

I have named the aluminum and chromium, if any extracted by enclosure, while iron is left behind. But in a cloth, and immerse the above-mentioned, the alumina about 30° – 40° C., occ. alkali. An insoluble compound of yellow powder gradual nesium is left, to be mistaken,

salt, and chloride of ammonium, and then boiling the precipitate with caustic soda for a couple of hours, after it had been collected and washed. On washing and testing the large portion of the precipitate which remained undissolved by the soda, I found that it contained an abundance of alumina.

Abich supposed the precipitate to be a mere compound of alumina and magnesia, like the mineral spinel, and proceeded to support this view by the following experiment:—Having weighed out quantities of alum and Epsom salt in such proportions that the oxygen ratio of the alumina to the magnesia was as three to one, he dissolved each of the salts in water, and treated the solution of sulphate of magnesium with so much chloride of ammonium, that the liquid no longer became cloudy on the addition of ammonia. He then added this magnesium mixture to the alum solution, saturated the whole with ammonia, collected the precipitate upon a filter, and tested the filtrate for magnesium. Since scarcely a trace of that element could be found in the filtrate, he, naturally enough, concluded that the magnesia had been precipitated by virtue of its affinity for alumina.

Abich's conclusion that a more or less definite aluminate of magnesium may be formed by precipitation, even in presence of chloride of ammonium, would seem to be supported, moreover, by his own analogous experiments on the precipitation of magnetic oxide of iron, in the wet way (*loc. cit.*, p. 353), and by the recent observations of Nichols (*American Journal of Science*, 1869, vol. xlvii., p. 16), "On the Precipitation of Insoluble Chromites of Magnesium by the Addition of Ammonia to Mixed Solutions of Salts of Magnesium and Chromium."

On examining into the matter, however, by direct experiment, it does not appear that the foregoing conclusion is justifiable. On the contrary, I find, in conformity with the statement of Fresenius ("Quantitative Analysis," London, 1865, p. 369), that it is possible so to precipitate the alumina by ammonia from a mixed solution of aluminum and magnesium, highly charged with chloride of ammonium, that no magnesium, or only an insignificant trace of it, will be dragged down.

It is noteworthy that the manner in which the ammonia is added to the solution has an important influence on the composition of the precipitate. I find, moreover, that far more magnesia will be dragged down by the alumina in case the solution contains a sulphate than if no sulphuric acid be present.

If the mixed solution of alumina and magnesia, charged with chloride of ammonium, be completely free from sulphuric acid, and if the ammonia water is added drop by drop to the hot solution (with constant stirring) until it is slightly in excess, the hydrate of aluminum thrown down will be entirely free from magnesium, or, at the most, will retain only a slight trace of that element. But if, on the other hand, an excess of ammonia be poured into the mixed solution rather quickly, a considerable quantity of the magnesia will go down with the alumina, even when no sulphuric acid is present.

If the solution contain the aluminum and magnesium in the form of sulphates, I find that as much as two equivalents of magnesia may be carried down by each equivalent of alumina, in case the ammonia is poured quickly into the solution. Probably a considerable larger proportion of magnesia could be thus dragged down by alumina from liquids more highly charged with the magnesium salt than mine were. But if the ammonia be added slowly, drop by drop, to the mixed sulphates of aluminum and magnesium, no more than 1 or 2 per cent of magnesia will be found in the dried precipitate.

I believe that if sulphuric acid be excluded, and the directions given by Fresenius for precipitating alumina by ammonia (*loc. cit.*, pp. 169, 369), be strictly followed, the precipitate may always be obtained practically free from magnesia.

A solution free, or nearly free, from sulphuric acid, was prepared for use in the foregoing experiments by precipi-

* Communicated by repeated the experiment by adding Department, Royal Institution of a mixture of alum, Epsom

tating a dilute (but as I would believe, not sufficiently dilute) solution of ammonia-alum (containing 1.3 grms. of Al_2O_3 to 750 c.c. of water) with ammonia, dissolving the washed precipitate in chlorhydric acid, and again precipitating, washing, and dissolving in the acid. The final solution of chloride of aluminum still contained a trace of sulphuric acid, but was thought to be pure enough for use.

To test the influence of the rapid addition of ammonia upon the amount of magnesia precipitated from solutions free from sulphuric acid, several quantitative determinations were made, with the following results:—To 50 c.c. of the above-mentioned solution of alumina in chlorhydric acid, containing 0.2575 gm. Al_2O_3 , there was added 0.1 gm. of pure, dry magnesia, so that the proportion of MgO to Al_2O_3 should be as 1:1, and about 5 grms. of chloride of ammonium. The solution was diluted to the volume of about 700 c.c., heated to boiling, and a considerable excess of ammonia water was quickly poured into it. The filtrate from the well-washed precipitate was evaporated to a small bulk, and the magnesia contained in it was precipitated by diphosphate of sodium. In the filtrate there was found 0.0854 gm. of MgO . Hence it appeared that $0.1 \times 0.0854 = 0.00854$ gm. of MgO had been carried down by the alumina. In two other experiments, performed in the same way 0.0798 gm. and 0.0964 gm. MgO were found in the filtrates. Magnesia was detected also in each of the three alumina precipitates:

The following experiments, on the other hand, were made with mixtures of Epsom salt and ammonia-alum. The solutions were made in each case by dissolving 1.23 grms. of Epsom salt and 2.2675 grms. of ammonia-alum, respectively, so that the proportions of alumina and magnesia in each mixture should correspond to the formula $2\text{MgO}, \text{Al}_2\text{O}_3$.

I. Four solutions were made by dissolving the above quantities of alum and Epsom salt, together with 10 grms. of chloride of ammonium, in 750 c.c. of water; the solutions were heated to boiling, and to two of them ammonia-water was added, drop by drop, to slight excess, with constant stirring; while to the other two a considerable excess of ammonia was added, all at once, before the mixture was stirred. All four mixtures were filtered as soon as possible after the addition of the ammonia. After ignition, the first pair of precipitates weighed, respectively, 0.2581 gm. and 0.2641 gm.; the other pair weighed 0.4965 gm. and 0.491 gm. On adding disulphate of sodium to the filtrates from the first pair of precipitates, copious precipitates were produced immediately; but with the filtrates from the second pair it was only after standing over night that slight crystalline precipitates of phosphate of magnesium and ammonia could be detected upon the sides of the beakers. It should be remarked that the experiments in this paragraph were made subsequently to those in paragraphs II. and III.

II. A number of solutions made by dissolving alum and Epsom salt (taken in the above mentioned proportions) in about 400 c.c. of water, were mixed with large quantities of chloride of ammonium, and then heated to boiling and precipitated by the addition of a considerable excess of ammonia, added without special care or forethought. After ignition in a platinum crucible over a plain Bunsen burner, the precipitates weighed, respectively, 0.36 gm.; 0.5232 gm.; 0.5499 gm.; and 0.521 gm.; while the sum of the weights of Al_2O_3 and MgO in the solutions taken amounted to only 0.4575 gm. Whence it appeared that some sulphuric acid is apt to go down with the alumina and magnesia. Abich himself (*loc. cit.*, p. 319), noticed a somewhat similar precipitation of sulphuric acid in conjunction with alumina and magnesia, and it is well known, for that matter, that some sulphuric acid is readily retained by alumina. H. Bley (*Journal für Praktische Chemie*, 1846, vol. xxxix., pp. 1—23), has, in fact, shown by quantitative experiments, that large amounts of sulphuric acid may be

dragged down by the alumina precipitated from solutions of alum.

It is to be observed, for the rest, that Abich, in his experiment of precipitating alumina and magnesia in equivalent proportions, operated with solutions of the sulphates of these substances. As now appears, it is hardly possible that he could have arrived at his erroneous conclusion if the solutions upon which he experimented had been free from sulphuric acid.

III. Seeking to avoid, if possible, this carrying down of sulphuric acid, I made other experiments, in which 10 grms. of chloride of ammonium and 750 c.c. of water were used in conjunction with the alum and Epsom-salt. The first precipitate obtained from such mixtures weighed 0.4567 gm., and the next 0.4754 gm., after long-continued heating over a plain Bunsen burner. In order to gain some idea of the proportion of sulphuric acid in this second precipitate, it was repeatedly heated over a gas blast-lamp for periods of ten or fifteen minutes, with the following results:—Weight of precipitate after plain Bunsen burner, 0.4754; after first blast, 0.4434; after second blast, 0.4334; third, 0.4317; fourth, 0.4314.

On a third trial, where the ammonia happened to be added strongly, the precipitate weighed only 0.255 gm. Since the pure alumina in the mixed solution amounted to 0.2575 gm., I was led by this remarkable result to make the experiments which have been recorded above, in paragraph I.

It is noteworthy that the appearance of the precipitates produced by the quick addition of ammonia is dissimilar according as they are obtained from solutions free from, or charged with, sulphates. The precipitates thrown down in this way from solutions of alum and Epsom-salt are dense and very difficult to filter; while those obtained from solutions of chlorides resemble ordinary precipitated hydrate of aluminum.

Before I had satisfied myself that it is easy to precipitate alumina almost free from magnesia by the method above described, I made several attempts to estimate the proportion of aluminum and magnesium in these insoluble basic sulphates, without, however, obtaining any very satisfactory results. The method of analysis employed was that of Deville (*Journal für Praktische Chemie*, vol. lx., 9), based upon the decomposability of nitrate of aluminum at a moderate heat. This process seems to yield good results when properly applied; but I experienced some trouble with it at first, from attempting to operate upon the mixed precipitate after it had been ignited. The ignited precipitate is scarcely at all soluble in hot concentrated nitric acid, even when the acid is made to act upon it for a long time; and it is not altogether easy to obtain a good separation of the magnesia and alumina after the precipitate has been made soluble by fusion with an alkali. The ignited precipitate can, of course, be dissolved in nitric acid after fusion with caustic or carbonated alkali; but, for my own part, I prefer not to ignite. The best way is to dissolve the moist precipitate immediately in nitric acid, to determine the alumina and magnesia in it, after Deville's directions, and to estimate the magnesia in the original filtrate for the sake of control.

I tried to decompose the ignited precipitate by fusion with nitrate of potassium, but abandoned the process on account of the risk of some material being carried off by the gases which are evolved as the nitrate decomposes.

When a very small quantity of the ignited precipitate was heated intensely with carbonate of calcium, over a blast-lamp, it became easily soluble in nitric acid; but, when as much as 0.3 to 0.4 gm. of the precipitate was operated upon, I could not obtain complete solution in this way. In using Deville's method, care should be taken to obtain nitrate of ammonium which is entirely free from non-volatile substances.

In attempting to analyse the mixed precipitate of alumina and magnesia obtained from Epsom-salt and alum, I was continually annoyed by the circumstance

that small quantities of alumina were dissolved, together with the nitrate of magnesium, by the solution of nitrate of ammonium. But I now suppose that this soluble alumina was derived from some of the basic sulphate in the precipitate, which had escaped decomposition when the precipitate was ignited.

Boston, April, 1870.

THE FIRE ALARM TELEGRAPH OF NEW YORK CITY.*

THE Fire Alarm Telegraph is designed, first, to enable any person to send a quick reliable telegraph message to the Central Station, indicating the existence of a fire near the spot from which the message is sent; and secondly, to enable the receiver of such a message to report instantly to as many other stations (the most important of which, of course, is the engine houses) as may be deemed advisable.

It is essential to the useful working of such a system that it should be always ready to respond instantly to the demands upon it; that the message sent should be positively reliable; that the condition of the out-door structure should at all times be under complete inspection of the Central Office; that an ordinary injury to the out-door structures may be instantly known and quickly repaired; that this injury, if not extensive may be of no serious detriment, and that a printed record of the transactions of the day, and the fidelity of those in charge, shall be produced. Such are the requirements of a perfect fire telegraph. How they are met will require an explanation in full detail of the construction, the machinery, and their varied combinations.

Lines.

These are so built that only a few stations are embraced in each, and they are so interwoven that contiguous stations are upon different lines, so that an injury to one line, which might put one station out of order, would have no effect upon the next nearest station—because that one would be placed in connection with a distinct and separate line. The wires are very strong, and of unusually high conductivity, so that the currents of electricity may flow through without impediment. The various lines extending from the Battery to Spuyten Duyvil all finally converge at the Central Office; one end of each of the 56 coming in from the North and the other end of each from the South. They leave the tall poles in front of the head-quarters, and are conducted carefully over its roof and down to heavy spars, whence they pass directly into the office. Here they are continued systematically to the batteries and instruments, but are so coloured as to designate the particular office which each has to serve.

Instruments.

The instruments and appliances at the Central Office consist of batteries, switch-board, register or receiver, indicator, transmitters, clock, repeater, and testing apparatus. The apparatus outside of the Central Office consist of automatic street signal boxes and mechanical gong strikers. All of these instruments are of the most perfect and elaborate construction, and most of them especially invented, designed, and made for the service of the complete system.

Batteries.

These are compactly arranged in series of shelves, so as to be easily accessible. The shelves and stands are very thoroughly insulated, and the peculiar form of the battery keeps it perfectly clean and dry. The zinc element of this battery is so formed as to make a cover to the glass jar, and thus prevent evaporation and the introduction of

foreign matter in the interior. All batteries give off currents of electricity of various power, according to the amount of chemical substances destroyed—but they are almost universally constructed so that the plates are plunged into a reservoir of acids or chemicals, which act directly upon the plates, unless labour is expended upon them to keep them protected, or upon the other parts of the battery to keep them clean. There is thus a large amount of destruction of material independent of that due to the evolution of electric force. This destruction is called local action. If this abnormal action can be guarded against, two beneficial results ensue—economy of material is secured and constancy of electric force and incidental labour is saved. The constancy of force is a very great consideration in a system where, for the first time, is introduced apparatus for the exact and instant measurement of electric force on every line. The experiments to secure this evenness of power and small consumption of material were carried on for more than a year upon the old lines of the New York fire telegraph. For more than twelve months a steady current was supplied by means of these batteries—the only labour required being the occasional supply of crystals. Without describing any other features of the battery, it may be simply said that the principle of the long endurance is found in the arrangement by which a steady but minute supply of active chemical is supplied continually; the supply is regulated to the requirements of the line. Only one-tenth of the expenditure of chemicals and labour are required. As it has been considered the best policy to keep the entire system of lines in a state of continuous and simple inter-communication, and as the expense of sustaining such batteries has been so much reduced, a very large number of cups are maintained, which, if extended, would occupy nine hundred feet in length. Beside these batteries others are provided for special purposes. The wires leading from these batteries are carried into the operating room symmetrically, and with a view to their easy and instant identification.

The Switch Board.

In all cases where many wires carry electrical currents into offices it becomes necessary at times to change the direction of these currents—to transfer them from one wire to another for various purposes—just as an engine and train of cars are diverted from one track to another. The same name is given to these devices, viz., "switch." When many wires are introduced, each requiring its switches for its various purposes, the assemblage is called a "switch-board." That of the New York fire alarm is superbly mounted, is nine feet in length, and has upon it upwards of five hundred switches, each performing its own special duty—but also arranged and grouped together so that very many may be moved by one common impulse, as when it is required to convert certain series on the entire number of lines from receiving to transmitting lines. To prevent oxidation the rubbing surfaces are heavily coated with platina. This combination gives the operator in charge the power of instantly applying to each and every line the changes which will be described. Unlike ordinary telegraph lines, the wires of the fire alarm do not pursue their course from the Central Office to the most distant station, and then dipping into the earth, consign the electric current to it, to be carried through it to the point of starting—thus making the earth the conductor for the return current—but the currents of the fire alarm return by wires. They leave and return to the office in what are called "metallic circuits." It is far better where lines are comparatively short to make the entire conductor metallic. If no connection is had with the earth in any part of the line, slight defects of insulation and contact with houses or poles do not seriously affect the working of the circuits. Exigencies occur when it becomes desirable to divide the lines for tests or repairs. Through the switch-board the operator turns his north end into the earth, with or without a battery; also the south end, with or without a battery; or, in case of the apparent

* Communicated by Professor Morton.

weakening of the battery, as made evident by a little tell-tale instrument yet to be described, he has the power of testing the exact force of his battery either off or on the line. He can also instantly exchange his enfeebled battery for his choice of several fresh ones, and he may change the course of the current of either of these fresh batteries, or, finally, he may place any one or all the lines in communication with the "repeater," thus changing them from receiving lines to transmitting.

Usually it is desirable to send out alarms, not only to all the alarm stations—that is, the engine houses, &c.—but also back again to the signal boxes throughout the whole island. The change, therefore, of all the lines from "signal" (that is, those that give the first alarm to the Central Office) to "alarm" (that is, those that receive the alarm sent out from that office) can be effected by almost a single movement on the switch-board. In order to give simplicity and order to the arrangement of this instrument, each and every line has its series of switches for these various changes arranged in rows. Every switch has designated upon it, in raised letters, the office it performs. Each and every line is alike, and each is numbered. They are also divided in sections of eight lines, so that it becomes quite easy to refer to any line without loss of time. Immediately in connection with the switch-board is a series of

Galvanometers.

These are instruments which measure the force of current on the line by deflection of a needle. A few degrees indicate a weak current, and many degrees a strong one. It is thus a valuable register of the state of the line—for the normal condition of the line being twenty degrees, ten degrees would indicate that the battery was becoming weak, and forty degrees would indicate that the battery was becoming stronger, which could not easily occur, or else that resistance at the line was lessened, or that the current had found some short road easier for it to travel than through all the length of the line with its numerous magnets. This measurement by degrees would be only a partial indication of the state of things. Hence to every one of these galvanometers is added that which makes the test an exact one. The "resistance" of a circuit or line is that obstacle it presents to the free passage of the electric current. Through a short circuit of large wire a large volume of electricity will pass and exercise powerful force upon magnetic instruments. Through a long circuit of fine wire the reverse is the case. Suppose a line five miles in length has included in it ten magnets, each of them being furnished with wire a mile long—or, as it is called, a mile "resistance"—the whole resistance would then be fifteen miles; but, if the current, instead of passing through all this length, proceed only two miles, and through only five magnets, and then gets back again, it is evident that it meets with only seven miles of resistance instead of fifteen. Hence we can often locate a trouble if we know the exact resistance of a line and compare it with the normal resistance of that line when all is in proper working order.

The process of ascertaining the exact resistance is as follows:—The needle of the galvanometer is made to deflect by the influence of a long coil of wire placed under it. When the current passes through the coil in one direction the needle deflects to the left; but we may add another coil of exactly equal power, so wound and placed that the needle may be pulled (by equal current) just as strongly to the right. Now, if we give a chance to the current from the same battery to go around these two coils at the same time, just as much will flow through each, and the needle being pulled in two ways with equal force, it will stand at zero. Again, if we add resistance to the wire connected with one coil and none to the other, then a greater part of the current will take the short road, and the coil without resistance will pull the needle the strongest. Hence, if we have a known adjustable resistance connected with the second coil, and the first coil is

connected with the line, when we have so altered and increased or decreased the known resistance that it equals the line resistance, and the needle stands at zero, the line resistance, of course, equals the measured resistance exactly.

The very resistance of lines thus tested daily, and recorded in a book, will be a complete history of the state of such lines. The instrument which contains the coils of measured resistance wires, by a combination of which any desired length of resistance is thrown in is called a "rheostat." In the Central Office it is arranged unlike any other such instrument, so that the changes may be made almost instantly, and at the same time can be read off in decimal numbers, indicating miles and tenths of miles.

The Register or Receiving Instrument.

This is the apparatus by which are recorded all the alarms that are sent into the Central Office, and all the tests of the day and night. The currents from the lines do not immediately proceed to this machine, but through the usual intervention of the relay magnet, of which fifty-six, in very compact form, are arranged upon the register-table. These relays act upon the register, and also, at the same time, upon an electric annunciator, by which the number of the line is indicated. When a signal is communicated to the Central Office from a street box, the first operation the box performs is to disturb and break up the current that steadily flows through the line at all times, and holds the relay magnet steadily charged. This break discharges the little magnet, its lever falls back, and, in so doing, instantly performs four operations. First, it throws down into view the number of the line called into action; it causes a bell to be rung; it starts the register wheel-work into revolution, and it prints a dot in ink upon a broad band of paper, which is rolled through the machine. If this single action was all that took place a single dot would be printed on the paper, which would run out about three inches and then the revolution would instantly cease, but it can be arranged that the paper shall run only two inches, more or less, before it stops. As long, however, as the line continues to be active by sending off signals, just so long will the paper keep running—always stopping, however, two inches, more or less, as adjusted, after the very last impulse from the line. This paper roll is about ten inches wide. Fifty-six pens, actuated by fifty-six magnets, are arranged beneath it, so that each and every one may be brought to bear upon the paper. Each one is connected with a separate line. The pens are numbered to correspond with the lines, from one to fifty-six.

Suppose that the signal 256 is to be sent in. The street box which sends this particular signal is one of those connected with line No. 21. The operation, then, of the bringing that box into action is, first, to start the paper roll into movement, and to throw into sight No. 21, to call into action the twenty-first pen, which, with great exactness, prints the signal 256 in ink upon the paper five times, and then the paper stops itself two inches after the last printed dot. Thus every signal sent over any of the lines is printed upon this same roll of paper either day or night. But the paper also records clearly another signal, which is automatic. A very fine regulating clock is suspended on the wall of the office. Precisely at each hour on the beat of the first second a type corresponding with the hour of the day strikes upon the paper roll and prints it. In the daytime the hour figures are different from those indicating the night hours. At the same moment a small bell is started, ringing continuously, notifying the operator in charge that the hour has come, and that he must proceed to test all his lines, and print the record that he has done so upon the paper. His duty is then to open for an instant each and every key on each and every line. These keys being arranged in groups of eight, may be struck, in groups or singly. The single touch of all these keys makes upon the register paper fifty-six dots corresponding with the fifty-six lines; and if no alarm of fire should come in to be recorded on the same paper, on

any one of the lines, then, at the commencement of the next hour, it would be printed in the same way as before on the paper, and another series of tests would be made. Thus, at the end of a day's operations the paper would show that, between the striking of every hour, day and night, every line had been tested and its good condition recorded upon paper: or, if its pen failed to make a record, explanation of the cause would be sought for and the difficulty obviated. Whatever fire might occur between any hours, would be also recorded in its appropriate place, and the paper thus becomes a record of the locality of every fire, the time that it occurred, and also the sound condition of all the lines. The clock which serves to actuate the printing of the hours upon the paper, can also be made easily, by the agency of certain switches, to strike the precise commencement of any hour upon each or all of the six hundred stations embraced in the entire system. In direct connection with this register, and its supplementary apparatus through the medium of the wires, are the

Street Boxes.

These boxes form, of course, a very important part of the apparatus of the system. They are fastened to the poles or engine-houses, and consist of an outer casing or house of iron, with the seal of the Metropolitan Fire Department on each, and a label covered with glass indicating to the public where the key which opens the box may be found. Every policeman is also furnished with a key, and every fireman, and the insurance patrol. When a fire occurs in the neighbourhood of a box, anyone who first obtains the key opens the outer box. Within it he perceives a second iron box, and, fastened to it, a handle to be pulled down. Printed directions are also visible, to guide in doing this simple thing in the right way, and also showing how it may be known that pulling the handle has been effective. The moment the opener of a box hears a response, he knows that his work is done. The officers in the department, who have keys for the inner box, to which the handle is fastened, discover, upon opening them, a third box, round, and tightly closed up from the air. On the outside of this third box is to be seen simply a brass arm, extending out to the right. This brass arm is fastened to the apparatus within the round box. The office of the pulling-down handle on the second box is to engage with and pull down this brass arm.

The action upon the arm winds up the machine within, which begins running down as soon as the brass arm is left free to move by the disengagement of the pulling-down handle.

Opening the round box (previously, however, removing the brass arm), within is found a very excellently finished piece of clock-work, driven by a spring, which is so attached outside of the frame that, if it breaks, another can be supplied without pulling the frame to pieces. The arm winds up the machine like a watch, but only a short distance. It begins to run down, and, in doing so, as the movement is controlled by a very perfect regulator, one of the wheels of the trains carries a "circuit-wheel," with teeth cut on it corresponding with the particular number-signal which the iron box represents. The office of the regulated clock-work is to carry this circuit-wheel very steadily and slowly around from one to five times, as it is set. Each time it revolves, its teeth strike upon springs, and the circuit is made to open and close correspondingly. Two system.

These are compactly arranged, and has a circuit-wheel with a thoroughly insulated, and the peccumber with certainty, five keeps it perfectly clean and dry Office, and it is printed on this battery is so formed as to be times. In addition to this jar, and thus prevent evaporat

* Communicated by Prof. is going correctly to the return signal from the

Central Office, and any and every desired signal which is sent out from that place. There is also a telegraph-key, by which messages, if necessary, may be sent; also a lightning-arrester; also a simple arrangement which, turned either right or left, divides the line into two parts, so that, if any accident should occur to interrupt the continuity of the circuit, preventing the current from going to or returning from the Central Office, the uninjured part of the line may be almost immediately utilised, and, instead of having ten boxes thrown out of use, the loss may be reduced to a single one. Thus a fire may burn down a pole or break a wire, but in a very few minutes the accident is known, and the line which has been broken is made into two short ones, until the time when it becomes practicable to re-unite the broken ends.

The other principal receiving-instruments in the Office consist of two extra and ordinary registers, by which the communications with the boxes which may be necessary for keeping the lines in perfect repair and good order are carried on, so as not to allow the main register to be cumbered by them. The apparatus for sending out the fire-signals, received from and through the machines just described, consist of the repeater, the supplementary repeater, and the mechanical gong-strikers.—*Journal of the Franklin Institute.*

ON THE

POTASSIO-COBALTIC NITRITE KNOWN AS FISCHER'S SALT, AND SOME ANALOGOUS AND RELATED COMPOUNDS.

By SAMUEL P. SADTLER.

THE composition of the double nitrate of cobalt and potash, known by the different names of "Fischer's Salt," and "Cobalt-yellow," has long been an open question. The following is a brief statement of the views advanced on the subject. Fischer,* the discoverer of the salt, made no analyses of it. St. Evre,† who re-discovered it, gave as a formula for it $K_2ON_2O_4 + CoON_2O_4$, but does not give the analytical data. Stromeyer‡ subsequently showed the incorrectness of this view, and wrote the formula $Co_2O_3, 2N_2O_3 + 3(K_2ON_2O_3) + 2H_2O$. This formula is peculiar in making the atom Co_2O_3 combine with 2 atoms of N_2O_3 . We shall discuss the formula and results further on. Erdmann|| first pointed out a distinction between the salt formed in neutral solutions and the salt formed in acid solutions, which latter he considers as a normal salt. He gives both

or, as we shall write it, $Co_2NO_2 + 6(KNO_2) + 3H_2O$ Braun,§ the last writer on the subject, passes most of the preceding work in review. He takes up Stromeyer's results, and rejecting his views as to the composition of the salt analysed by him, figures for it a number of ingenious but somewhat complicated formulæ. He considers that neither the "neutral salt" nor the "acid salt" of Erdmann can be regarded as anything but mixtures or "poly combinations," and for the first of them considered as such, he gives a still more ingenious and complicated formula. We quote it as reduced to its empirical form by Blomstrand:¶ $Co_6K_{59}N_{112}H_{20}O_{454}$.** Braun's own results are expressed first by a formula containing both

Co₂O₃ and CoO, then by one containing Co₂O₃CoO,N₂O₃ and N₂O₅ and finally by the following:—

The experiments made to settle its composition and the results obtained are as follows:—St. Evre ignited the salt in a stream of nitrogen. Nitric oxide was given off and the residue was a black oxide, which, on contact with HCl, gave Cl, and with C₂H₄O₄ gave CO₂. This I cannot regard as conclusive, as mere ignition *per se* will not break up the KNO₃, so that the residue was not pure, Co₂O₃; moreover the N₂O₃ in breaking up may have given an atom of O to form the Co₂O₃. Stromeyer found that NaHO and BaH₂O₂ decompose it on gentle warming, even with exclusion of air, separating the brown hydrated Co₂O₃ which dissolves in C₂H₄O₂ with a brown, and in C₂H₂O₄ with a green colour. This observation is of undoubted value. He says, also, that on mixing the neutral solutions, the precipitate is slow in forming, and forms by an absorption of O, as is shown by dipping the connecting tube under a cylinder of air or oxygen. Erdmann confines himself to an examination of this last observation of Stromeyer's, and finds that the "neutral salt" can be formed in an atmosphere of pure CO₂, and that therefore there can be no absorption of O in the case. Braun finds that KHO acts very little upon the salt, merely changing its colour from yellow to a dirty yellowish-green. NaHO, BaH₂O₂, CaH₂O₂ separate, at a boiling heat, the brownish-black hydrated Co₂O₃; this is confirmatory of Stromeyer's observation. Carbonate of silver heated with water and Fischer's salt, gave, with separation of the hydrated Co₂O₃, crystals of what, from Braun's description, were probably AgNO₂; KCy did not decompose it.

My own experiments directed toward the solution of the question of CoO or Co₂O₃ were as follows:—I found Erdmann's observations as to the formation of the "neutral salt" in an atmosphere of CO₂ correct. I added, by means of a funnel tube, a solution of KNO₃, boiled to expel the air, to a boiled solution of CoCl₂, placed at the bottom of a partially closed vessel, into which a strong stream of CO₂ had been passing for some time. The salt began, nevertheless, to form slowly. Wishing to sift the matter more thoroughly, I made a series of experiments in eudiometer tubes over mercury. Into a eudiometer tube, filled with mercury and perfectly free from air, I threw up a boiled solution of CoCl₂ and then one of KNO₃. The salt began to form soon at the juncture of the two liquids and then deposited steadily though slowly. After a number of hours not the slightest bubble of air was to be seen. The absence of all chance of oxidation here, either from air or excess of nitrous acid, shows, conclusively, the protoxide nature of this "neutral salt." The "acid salt" was formed in the same manner—first a boiled solution of CoCl₂, then acetic acid, and then a boiled KNO₃ solution. A rapid evolution of gas ensues, and the salt forms and falls in a layer on the top of the mercurial column; in another instance a small crystal of CoCl₂ was sent up, and then acetic acid, and then KNO₃. The formation of the salt was almost instantaneous, and the evolution of gas exceedingly rapid. Before drawing any conclusions from this, however, the action of acetic acid on KNO₃, out of access of air, was to be studied. Gmelin* states that, when treated with acid out of access of air, nitric oxide is evolved, while the liquid takes up NO₂ and N₂O₅. This evolution was found to take place readily over the mercury, and the gas answered to the test of ferrous sulphate, and was coloured red on admission of air, like the gas evolved in the formation of the salt. The question now is whether the liberated O is taken up in the formation of the salt to oxidise the CoO, to convert the excess of nitrite into nitrate. The question cannot be definitely settled until we have some delicate test for a small quantity of

nitrate in the presence of a large quantity of nitrite; but there is one thing which I regard as significant, Erdmann made one of his preparations of the "acid salt" by filtering the mixture of neutral solutions into pure acetic acid. Now the greater the excess of acid, the quicker would be the conversion of nitrite into nitrate, and we should look for a very small amount of the double nitrite salt. Yet it formed as readily, and analysis proved it to possess the same constitution as the other preparations. The inference from this is, that the sesquioxide-forming power of the Co is sufficient to enable it to take liberated oxygen.

Recourse was now had to analysis as a means of determining the question. Six distinct preparations of the salt in all were made and analysed. In preparing the salt, the distinction made by Erdmann in regard to the formation of different compounds in neutral and acid solutions, was recognised, and the salt was invariably formed in a solution, strongly acidified by acetic acid in the beginning, and kept so until the end by the addition of acid, if necessary. The salt of cobalt used was the chloride, and, in all but the first two preparations, the solution was boiled to expel air, and made acid. A strong solution of KNO₃ was then added, and the mixture was left to stand; six or twelve hours generally proved sufficient, and it was then filtered and washed, according to Erdmann's direction, with a solution of potassic acetate of about 10 per cent, which was displaced by 80 per cent alcohol. The salt was then dried, first over the water-bath and then in a water-oven, exactly at 100°. I saw no evidence of a decomposition at this temperature alluded to by Erdmann.

The results of full analyses of these six preparations warrant me, I think, in presenting the following conclusions:—

1. That Fischer's salt is a *Tri-potassic-Cobaltic-Nitrite*, its essential formula being

2. That it can be formed with 4H₂O, 3H₂O, 2H₂O, H₂O, or anhydrous, according to the degree of concentration of the solutions used, passing in colour from a light yellow to a dark greenish-yellow.

3. That in consequence of such dependence, we can, in most preparations, fix no absolute point, but are liable to have a mixture of salts of different degrees of hydration.

The analytical methods used in the analyses of the salt were the following:—

The Co was determined first together with the K, as a double sulphate having the invariable constitution Co₂K₆SO₄. This sulphate has a distinct fusing-point, and affords an accurate means of determination. It will be discussed further on. This is then dissolved, the solution made ammoniacal, and brought to boiling, when the Co is thrown down as CoS. This is roasted, and, after treatment with aqua regia and sulphuric acid, is weighed as neutral CoSO₄. Or the Co was thrown down from the solution of the double sulphates as peroxide by acetate of soda and chlorine, and then reduced by hydrogen to the metallic state.

The potash is then determined by difference.

The nitrogen was determined, either together with the H₂O by Gibb's modification of Bunsen's method, which will be again alluded to, or directly by volume with the Sprengel-pump.

The H₂O either as above, or by combustion with Cu in a stream of CO₂.

It will be seen that, while the general coincidence is well sustained, there are several decided deviations. We can only call attention to certain facts in explanation. 1. We probably have in some of these preparations, mixtures of the salts of different degrees of hydration. 2. The salt cannot be purified by re-crystallisation. 3. The acetate of potash with which the salt is first washed is, as Rose remarks, only removed with difficulty by the alcohol.

(To be continued).

NOTICES OF BOOKS.

First Principles of Chemical Philosophy. By JOSHUA P. COOKE, jun., Erving Professor of Chemistry and Mineralogy in Harvard College. Pp. 560. London and Cambridge: Macmillan and Co. 1870.

THE author of this work, the Professor in the celebrated American University, states, in his preface, that the object of his book is to present the philosophy of chemistry in such a form that it can be profitably made the subject of college recitations, and furnish the teacher with the means of testing the students' faithfulness and ability. The subject has been developed in a logical order, and the principles of the science are taught independently of the experimental evidence on which they rest. It is assumed that the student has already been made familiar with the evidence and with the more elementary facts which the philosophy of science attempts to interpret. The book is divided into two main divisions. Part I. contains seventeen chapters, including, besides, a clear and lucid introduction giving definitions. The chapters treat on: Fundamental Chemical Relations; Molecules; Atoms; Chemical Notation; Stoichiometry; Chemical Equivalency; Chemical Types; Bases, Acids, and Salts; Chemical Nomenclature; Solution and Diffusion; Combination; Molecular Weight; Crystalline Forms; Electrical

Relations of the Atoms; Relations of the Atoms to Light; Chemical Classification. Part II. is sub-divided into two main chapters, one of which bears title "The Perissad Elements," viz., hydrogen, fluorine, chlorine, &c.; the other "The Artiad Elements," viz., oxygen, sulphur, &c. The philosophy of chemistry is developed in this book according to the "modern theories;" careful attention has been given to chemical notation, and a method has been devised of writing rational symbols which, while it fully exhibits the relations of the parts of the molecule, condenses the formulæ, and saves space and labour in printing. The nomenclature usually current in our own Chemical Society has been adopted, but in the chapter on this subject the old names are given with the new. The metric system of weights and measures and the centigrade thermometric scale are used throughout. There are also added excellent tables of French Measures; Elementary Atoms; Specific Gravities of Gases and Vapours; and Logarithms and Anti-Logarithms, with a very correct and copious index.

As far as our recollection goes we do not think that there exists in any language a book on so difficult a subject as this, so carefully, clearly, and lucidly written. The author, moreover, deserves the thanks of all English students of chemistry and friends of science, for having entrusted the publication of his work to so well-known an English firm, and the publishers are equally praiseworthy for the excellent execution of a book, requiring, as it does for its completion, extreme care, as well as specially cut types for some of the formulæ. We recommend this work to all who desire to become thoroughly conversant with a somewhat intricate but very important subject.

Lecture Notes for Chemical Students. By EDWARD FRANKLAND, F.R.S., &c., Professor of Chemistry in the Royal School of Mines. Vol. I.—Inorganic Chemistry. Second Edition. Pp. 220. London: John Van Voorst. 1870.

THIS is the first part of a second and revised edition of Dr. Frankland's work. It is not a manual of chemistry in the ordinary sense of the word; for it says but little of the manufacture of chemical compounds: it scarcely alludes to their outward and sensible properties; but it gives many glimpses of their interior constitution. These Notes were originally published in one volume; but, at the request of numerous readers, the eminent author has divided the work into two parts, of which this volume forms the first. The author's aim has been to classify and systematise rather than to describe, and to furnish the student with a kind of skeleton of the science; it being the author's intention that the student should himself clothe and dress this skeleton with the already-known and daily-increasing facts of experimental research. To aid the student in that good and useful work, the titles of the works published by several eminent English, as well as foreign, authors of works on chemistry are quoted. The graphic notation of Dr. Crum Brown, which was adopted, in the former edition, to illustrate important constitutional formulæ, has been somewhat modified in the present, by the omission of the circles surrounding the symbols of the elements; the author's previous opinion, that these circles render the formulæ more intelligible to beginners, not having been confirmed in practice. Since, however, during the time which has elapsed since the publication of the first edition of this work, this modified form of graphic notation has been adopted by a large number of chemists, it is desirable that the student should use that form which is most extensively employed, and which, as regards constitutional formulæ, has become almost a necessity to give precision to that hypothetical reasoning which stimulates to further research.

Since this work was first published, many of its peculiar novelties have become, as might be expected, generally known and appreciated, if not as yet generally adopted

* Acetate of potash probably not all washed out by alcohol.

† Unaccountably high.

‡ *Anal. Ch. Sechste Auflage, Zweiter Band, p. 128.*

by chemists. The contents and general arrangement of this volume is not altered, but it has been increased by the addition of the constitutional formulæ of minerals. The opening chapters—Introductory, Chemical Nomenclature, Chemical Notation, Compound Radicals, Atomic and Molecular Combination—are so tersely worded that any student may readily and quickly catch the meaning intended to be conveyed to the mind. The whole book is an *epitome*, but of great utility, since the eminent author has succeeded in rendering modern chemistry, with all its at first sight great intricacies and difficulties, readily understood, whilst the disciple gradually ascends from the more simple to the more complex matters, and is almost imperceptibly brought into the domain of organic chemistry.

Eminent Men of the Day. Photographed by G. C. WALLICH, M.D. Scientific Series. London: John Van Voorst, Paternoster Row. 1870.

BIOGRAPHIES and autobiographies of those we have known, and who are honoured by us for their worth, their discoveries, and scientific attainments, are valuable, and we could ill afford to dispense with these memorials. But, after all, there is nothing more pleasant than to possess a faithful representation of the features and expression of those holding a foremost place in the ranks of science; and, in looking over these photographs, it is easy to recall the various discoveries which have led to well-deserved honours and world-wide fame.

The volume contains most characteristic likenesses of:—General Sir Edward Sabine, K.C.B.; Sir Roderick Impey Murchison, Bart., K.C.B., F.R.S.; Professor Owen, D.C.L., F.R.S.; George Benthams, F.R.S.; Thomas H. Huxley, LL.D., F.R.S.; Joseph Dalton Hooker, C.B., D.C.L., LL.D., F.R.S.; Sir Charles Lyell, Bart., F.R.S.; John Tyndall, LL.D., F.R.S.; Sir William Logan, F.R.S.; Professor Stokes, M.A., D.C.L., LL.D., F.R.S.; Professor A. C. Ramsay, LL.D., F.R.S., F.G.S.; Viscount Walden; William Lassell, F.R.S.; Joseph Prestwich, F.R.S.; Rev. J. B. Reade, M.A., F.R.S.; and Professor Williamson, F.R.S.

We wish that the series could be greatly extended, so as to include many more in each department of science. We should like to see, in addition to this volume (which contains, for the most part, the presidents of the various scientific societies), a volume containing portraits of the most distinguished chemists; another, of those who have devoted years of labour to physical researches; another, of eminent geologists, &c. And we hope that this volume will have such an extensive circulation, and be so well received, that Dr. Wallich will decide upon issuing at least one more volume of scientific celebrities.

The photographs are well executed, and handsomely mounted and bound; and the book cannot fail to be highly prized.

The Fuel of the Sun. By W. MATTIEU WILLIAMS, F.C.S., &c. Pp. 222. London: Simpkin, Marshall, and Co. 1870.

UNDER this title, which, to ordinary minds, might appear absurd enough to suggest doubts as to the writer's sanity, the author has made an attempt (and a very bold one) to explain some of the greatest mysteries of the Universe.

Mr. Williams certainly deserves extraordinary credit for this work; for, although it is quite true, as he himself says, that he fairly exposes himself to the accusation of extreme presumption, the whole work bears testimony of sound and deep study of physical sciences, and of an acute mind and great sagacity for observing and applying facts. And, although the work abounds in speculations as yet not proved (and it may be doubted whether man ever will be able, while on this globe, to learn and to prove the real truth), they are here lucidly set forth in print, and are therefore suggestive of good, inasmuch as their perusal may assist others to elicit new facts.

The following quotation will give, perhaps, the key-note of the book:—

"The sun, according to my hypothesis, is a hollow flame, with dissociated combustible gases within it, and a nucleus of some kind within them. It differs from the hollow flame of a candle in the very important respect of not being dependent upon external oxygen for its support. It contains all the materials of combustion within itself; but this combustion, or combination, is restrained from proceeding explosively inwards by the dissociating force of the high temperature of the inner gases.

"When two substances, such as oxygen and hydrogen, combine chemically, they evolve an amount of heat exactly equivalent to that which is required to drive asunder the constituents of an equal quantity of the compound which they form; and, therefore, the amount of combination or combustion that can take place in a given mixture of such elementary gases is limited by the quantity of heat which surrounding bodies are capable of abstracting. To illustrate this, let us conceive the case of a certain quantity of the elements of water heated exactly to the temperature of dissociation, and confined in a vessel the sides of which are maintained externally at precisely the same temperature as the gases within, so that no heat can be added or taken away from the gases. No sensible amount of combination could now take place, as the first infinitesimal effort of combustion would set free just the amount of heat required to decompose its own result. In like manner, if a quantity of aqueous vapour were subjected to the same conditions, there would be a corresponding equilibrium; and no sensible amount of dissociation could take place, as the first effort of dissociation would be attended with a conversion of heat, and consequent loss of temperature, which would be exactly compensated by the instantaneous reunion or combustion of the infinitesimally small quantity of dissociated water.

"Let us now suppose a modification of these conditions; viz., that the vessel containing the dissociated gases at the temperature of dissociation shall be surrounded with bodies cooler than itself, *i.e.*, capable of receiving more heat from it than they radiate towards it. There would then take place just so much combustion as would set free the amount of heat required to maintain the temperature of the vessel at the dissociation-point; or, in other words, combustion would go on to the extent of setting free just as much heat as the gaseous mass was capable of radiating, or otherwise transmitting to surrounding bodies; and this amount of combustion would regularly and steadily continue until all the gases had combined.

"We have only to give this hypothetical vessel, a spherical form and an internal diameter of 853,380 miles, to construct its enveloping sides of a thick shell of aqueous vapour, and then, by placing in the midst of the contained gases a central nucleus of solid or liquid matter, we are hypothetically supplied with the main conditions which I suppose to exist in the sun."

We purposely abstain from entering into further details; since, by thus dissecting, we might risk misrepresenting the contents of a work which abounds with valuable information on cosmography in its widest sense.

The work is very readable; and the typographical execution is also excellent.

CORRESPONDENCE.

ANALYSTS' FEES.

To the Editor of the Chemical News.

SIR,—Some time since, a few letters appeared in your paper on high and low analysts and their fees. Now, in the north of England, people will not pay the fees that more favoured localities obtain; but I was not prepared for a circular (which I beg to enclose) which informs the

world that a Ph.D. and F.C.S. will execute any complete analysis for £1 rs., and anything less complete for ros. 6d. He also states that he holds testimonials from the most renowned scientific men of the day; and winds up by advertising himself as a chemical broker.

How hard, indeed, is the lot of the analyst whose views of professional status will not permit of dabbling in shop-keeping!—I am, &c.,

OLD PRICE.

STELLARTON ACID-WATER ANALYSIS.

To the Editor of the Chemical News.

SIR,—I have just received Nos. 548 and 549 of the CHEMICAL NEWS, and learn from them that my late paper "On the Stellarton Water," published by the Chemical Society, has been the subject of discussion. I am obliged to Dr. Gladstone for showing Mr. Spiller how my statement as to free sulphuric acid being present is quite admissible, and for explaining to him the meaning of the word *underlying* (the rocks and coal dip at an angle of 26°).

With regard to alumina being given in the deposits and not in the water, I may say that analysis was made on *filtered* water, and that insoluble aluminous matter may have been introduced into the boilers on the "fibres, apparently, of roots" mentioned as found in the incrustation. The amount present was quite trifling. I find it stated, however, in my note-book that there was a trace of alumina in both waters; and no doubt I ought to have mentioned this substance among the other ingredients (I suppose I thought it too small in amount).

As for silica mentioned in the water and not in the deposits, the amount dissolved in the water was only (at most) 0.52 of a grain to the gallon. And, being soluble, why should it necessarily have been in the deposit? and why, under the circumstances, was it material to look for it if in small amount?

Hoping that some useful discussion on essential points (especially as to arrangement of results of water analysis) may arise from Mr. Spiller's criticism of my paper, I am, &c.,

HENRY HOW.

University of King's College,
Windsor, Nova Scotia, June 10th, 1870.

MISCELLANEOUS.

The Cryophorus, &c., with Bunsen's Pump.*

Professor Cooke finds that the Bunsen Pump will serve admirably for freezing the cryophorus by evaporation of ether. The lower bulb is wrapped about with several folds of cotton, which are drenched with ether, the tube being passed through an india-rubber cork fitting into the tubulure of a receiver, which is placed upon an air-pump plate connecting with the Bunsen pump. The cold produced by the rapid evaporation of the ether in vacuo, causes the water in the upper bulb to freeze rapidly. Bunsen's pump is applicable not only in this but in many other cases in which the condensation of moisture, or the presence of corrosive gases and liquids forbid the employment of the common air-pump. As for example, the familiar experiment of making tepid water boil violently when placed in a partially exhausted atmosphere. Indeed, Bunsen's pump may be made to take the place of the air-pump for almost all purposes, and forms a most valuable adjunct not only to the laboratory, but also to the lecture-table. In the filtration of large quantities of acids, alkalies, &c., a funnel may be employed of a half-gallon capacity or larger, and closed by means of sealing-wax with a conical plug of pumice of about $\frac{3}{4}$ inch thickness. The bulb of the funnel is then passed through the

tubulure of a receiver as above. Besides this useful contrivance, Professor Cooke has found the Bunsen filter to work well where large masses of precipitate must be dealt with. In this case a zinc cone, three inches in depth, which is cut, formed up and soldered in the same way as the small platinum cone, described by Bunsen, is fitted into a large funnel. Several pounds of precipitate may be thrown upon a single thickness of filter paper, which is supported by a cone of this description, and washed rapidly and completely under atmospheric pressure. If it is not desired to preserve the filtrate and wash-water, the tube of the filter may be fitted directly into the exhaust pipe of the pump, and the liquid carried off along with the air. Such arrangements as those detailed above would greatly economise the time, labour, and working space of pharmacutists and manufacturing chemists.—*Journal of the Franklin Institute.*

NOTES AND QUERIES.

Bromine.—(Reply to "J. H. Watson.")—Consult the latest edition of Rose's "Analytical Chemistry," recently published in the German language; or Fresenius's "Quantitative Analysis," latest English edition.

Persulphide of Hydrogen.—(Reply to "W. B. G.")—Consult "Handbook of Chemistry," by Gmelin; Watts's "Dictionary of Chemistry;" and "Jahresbericht über die Fortschritte der Chemie," von Kopp and Will; all of which works you may inspect at the Library of the Commissioners of Patents.

Lead Roofing.—The lead on the ridgings of my house dissolves with rain, and streaks of whitish-looking stuff runs irregularly over the slates from these various ridgings. As the slates are much exposed to view, it looks very ugly in dry weather. Can any one suggest a remedy?—**SLATES.**

Work on Sulphur.—Can any of your numerous correspondents kindly inform me of a book on sulphur, giving a lucid explanation of its extraction from clays, pyrites, &c.; the quantity of fuel used, the percentage of sulphur which would be payable to work, and the description and average cost of plant necessary for its production as a marketable article? I have looked in Watts's "Dictionary," Muspratt, and several other works, but the information is scarcely so full as I require.—**GEORGE CRAMPTON.**

Latest Novelty in Orchil Paste.—The great advance in the price of orchil weeds has put the manufacturers of weed colours upon their mettle. Many sophistications have become known to consumers. So the last "improvement" is to buy up spent weed from parties who make orchil liquor for their own consumption, and incorporate it with the recent weed in the process of manufacture. Thus a very solid paste is obtained, in which the microscope reveals nothing objectionable. The only method of detecting this ingenious dodge is to compare the tinctorial power of the sample against that of a genuine sample equally low in moisture.—**W.**

TO CORRESPONDENTS.

Richard Weaver.—There is no material improvement in the second edition.

J. L. Sinclair (Auckland).—The specimens of auriferous quartz, together with your letter, have been received, for which please accept our thanks.

W. H. Walcott is thanked for his kind communication.

J. Phin.—We have pleasure in acceding to your request. Your book has been received.

D. T. Hughes.—Received with thanks.

The Secretary of the Royal Society is thanked for his communication.

F. H. T. A.—We should recommend Watts's "Dictionary of Chemistry," (Longmans), £7 3s., Miller's "Elements of Chemistry," 6os., (Longmans), Powne's "Manual of Chemistry," (Churchill), 14s., Odling's "Outlines of Chemistry," (Longmans), 7s. 6d., Bowman's "Practical Chemistry," (Churchill), 6s. 6d., Bowman's "Medical Chemistry," (Churchill), 6s. 6d., Roscoe's "Elementary Chemistry," (Macmillan), 10s., Bloxam's "Laboratory Teaching," (Churchill), 5s. 6d.

J. B. Lippincott & Co.—Received.

W. H. Wood.—Your communication shall receive early attention. It arrived too late for this week.

J. Wilson.—You had better write to the Editor of the *Annales du Gémé Civil*. We do not know the address of Dr. Reinsch. Dr. Otto's memoir was in the *Journal of the Franklin Institute*, for January, 1870, which is published in Philadelphia, U.S.A.

THE CHEMICAL NEWS.

VOL. XXII. No. 554.

PRELIMINARY NOTE ON THE PREVENTION OF MOULDINESS IN AQUEOUS SOLUTIONS OF TARTARIC ACID.

By WILLIAM H. WOOD,
Middlesbro'-on-Tees.

IN July, 1867, I commenced experiments (which I have continued at various times since, and of which all are still in progress) to determine whether it was possible to prevent the formation of mould which usually occurs in aqueous solutions of tartaric acid a short time after their preparation.

I first tried the addition of creosote, of which I found a single drop effectual in preserving an ounce of solution of 1 part of acid in 2 parts of water.* A week or two since, a friend of mine called my attention to a very similar method of preservation, or prevention, in Bowman's "Practical Chemistry" (5th edition, p. 247), where it is stated, in a foot-note, that the mouldiness "may be prevented by adding a very minute quantity of carbolic acid, which does not interfere with the uses of tartaric acid in analysis."

I do not write to claim priority in the discovery of the above-stated fact, but to make known that, so far, my experiments lead or point to the conclusion that, if a solution of tartaric acid in water, whether mouldy or not, be filtered, and then boiled for a short time (say ten minutes), it will not afterwards become mouldy, whether corked or stoppered up in a bottle, or left exposed to the air.

The details of the various experiments I reserve for a future and longer paper, when I have ascertained the results of several experiments made for confirmation. The statement just made will, in my opinion, if confirmed, be important as bearing on the so-called "spontaneous generation" controversy, and will, I think, throw some light on it. A similar mode of experiment I intend to apply to citric acid and various other substances whose solutions are similarly decomposed. I shall also endeavour to ascertain the cause of the non-formation of the mould.

The delay in the publication of the above experimental result arises from the length of time which an experiment of this kind must be in operation before reliable results can be obtained.

June 28th, 1870.

ON THE FORMATION OF OZONE BY RAPID COMBUSTION.

By O. LOEW,
Assistant in the Chemical Department of the College of the
City of New York.†

ACCORDING to the view of Schönbein, every slow oxidation is accompanied by formation of ozone, common oxygen not being able to combine directly with the elements. In 1858, Clausius advanced the hypothesis that ozone is oxygen in the state of free atoms, while common oxygen consists of a molecule of two combined atoms. But the later investigations of Andrews and Tait, Babo, and Soret, upon the volume of ozone have not supported this

* Strength recommended in Galloway's "Qualitative Analysis," for analytical purposes.

† Read before the Lyceum of Natural Science, New York.

notion; and Clausius has modified his hypothesis accordingly, now believing that ozone is a combination between an atom and a molecule of oxygen. This combination is but a loose one; and the power of oxidation resides in the third atom of oxygen, which combines directly with other substances, leaving common oxygen behind. This constitution of ozone may be represented by the following formula:— $3[OO] = 2[OOO]$.

The oxidation of a metal by ozone is shown by the equation, $[OOO] + M = MO + ([OO])$.

When we now take into consideration that ozone and antozone together give common oxygen, we must conclude that antozone is oxygen in the state of free atoms. Furthermore, we see that common oxygen can be converted, according to circumstances, either into ozone or antozone. It seemed to me that, in every combustion, even the most rapid and energetic, an intermediate decomposition of the molecule of common oxygen must take place if the single atoms will enter into combination with the elements, and that ozone or antozone would be detected in a flame if the high temperature would not destroy it again as quickly as it is formed.

To prove this conclusion, I blew a strong current of air through a tube, into a flame of a Bunsen's burner and collected the air in a beaker glass or balloon. I was thus able, in a few seconds, to collect enough ozone to readily identify it by its intense odour, and by the common tests.

This observation shows that, not only in slow oxidation, but also in rapid combustion, an intermediate formation of ozone takes place,* and that it can be separated in the proper way.—*American Journal of Science*, vol. xlix., p. 369.

REMARKS ON THE ALKALIES CONTAINED IN THE MINERAL LEUCITE.

By J. LAWRENCE SMITH.

IN examining recently many of the silicates containing alkalies, my attention has been called to leucite, and it is on that mineral especially that I would now remark, reserving for another time my observations on the other silicates.

The specimens of leucite examined came from four localities—Vesuvius, Andernach, Borghetta, and Frescati. They were about as good specimens as are obtained from those localities, although all of them were not equally pure. The alkalies found in each calculated as potash were—

Vesuvius	21.85
Andernach	20.06
Borghetta	20.68
Frescati	20.38

The specimen from Andernach was analysed for the silica, &c., and found to contain—Silica 54.75, alumina 23.08, and 1.55 of oxide of iron; this last seemed to be mechanically disseminated through the crystals.

I say above in relation to the alkalies "all calculated as potash," for the reason that there is a notable quantity of rubidium and cesium present in all the specimens above mentioned. In fact, by the method adopted in testing for these alkalies abundant indications are obtained of the presence of rubidium and cesium (the last not so readily), even when operating on but $\frac{1}{4}$ a grm. of the mineral. I am now engaged in working out a method of estimating quantitatively rubidium and cesium in the presence of other alkalies; by this method, not yet perfected, the quantity of these alkalies in leucite is found to be about 9-10ths of 1 per cent of the entire mineral.

Of course it is not at all remarkable that the potash in the different specimens of leucite should be the same; but it is a matter of interest to know that, from whatso-

* Compare the observation of Pincus in the article "On Nitrication," *American Journal of Science*, II., vol. ii., p. 238.

ever locality it comes, this minute quantity of rubidium and caesium occurs with it. On some future occasion I hope to be able to bring together certain generalities in this connection of more or less interest to mineralogists.

I have also detected rubidium in $\frac{1}{4}$ gm. of margarodite and Warwick mica, and have failed to detect it in apophyllite, Thomsonite, pecholite, elaeolite, chesterite, cancrinite, and other silicates.—*American Journal of Science*, vol. xlix., p. 335.

ON THE COMPOSITION OF THE ACID-OXALATES OF POTASSIUM, AMMONIUM, AND SODIUM.*

By WILLIAM RIPLEY NICHOLS,
of Boston, Massachusetts.

Binoxalate of Potassium.

THE composition of this salt was formerly held to be expressed by the formula† $\text{KO}, \text{C}_4\text{O}_6 + 3\text{HO}(\text{C}_2\text{KH}\Theta_4 + \text{aq.})$; and this formula is still given by Gmelin, Watts, and others, as that of the commonly-occurring salt.

Rammelsberg,‡ on the other hand, describes the salt obtained by neutralising a certain quantity of oxalic acid with carbonate of potassium, and adding an equal amount of oxalic acid, as corresponding to the formula—

Marignac,|| having afterwards partially analysed this salt, concluded that the correct formula was—

and that the crystals contained no water of crystallisation. He differed from Rammelsberg as to the system to which the crystals should be referred; and the latter afterwards acknowledges the correctness of Marignac's views as to the crystalline form, and, without repeating the analysis of the salt, seems satisfied to accept the formula assigned by Marignac.

I have prepared this salt in the manner indicated by Rammelsberg, and find that its composition agrees with the formula originally given by him.

	530.44	100.00							

In these analyses, I determined the potassium as carbonate, by igniting a portion of the finely-powdered crystals in a covered platinum crucible, raising the heat very gradually in order to avoid loss by projection, to which, as Marignac hints, this salt is particularly liable. The oxalic acid was determined by titration with a solution of permanganate of potassium, standardised against pure oxalic acid. The hydrogen was determined by igniting the salt, in a combustion-tube, in a stream of dry air, and collecting the water in a weighed chloride of calcium tube.

Had Marignac determined the hydrogen in his salt, he would have found his formula to be inadmissible.

In regard to the acid-oxalate described by Graham (*loc. cit.*),† it is extremely doubtful whether there be such a salt. Rammelsberg‡ doubts its existence; and I have myself been unable to procure it. I added to a hot solution of a known quantity of oxalic acid half the carbonate of potassium necessary to neutralise it. The crystals which formed in the hot solution (A), those deposited from the solution at the ordinary temperature (B), as well as those deposited when the solution was artificially cooled to a considerably lower temperature (C), proved to be the quadroxalate, $\text{C}_2\text{KH}\Theta_4, \text{C}_2\text{H}_2\Theta_4 + 2\text{aq.}$

	Calculated.	A.			B.		C.
					I.	II.	
K_2O	94.22	18.54	—	—	18.41	18.53	—
$4\text{C}_2\text{O}_3$	288.00	56.67	56.23	56.52	—	56.86	56.33
$3\text{H}_2\Theta$	54.00	—	—	—	—	—	—
4aq.	72.00	24.79	—	—	—	—	—
	508.22	100.00					

In these estimations, the potassium was determined as carbonate, by ignition; and the oxalic acid by titration, as in the preceding case.

I analysed several samples of commercial "binoxalate of potash," but each sample proved to be quadroxalate.

Binoxalate of Ammonium.

This salt was prepared by neutralising a certain quantity of oxalic acid with ammonia-water, and then adding an equal quantity of oxalic acid. Analysis showed the composition of the salt to be $2(\text{C}_2(\text{NH}_4)\text{H}\Theta_4) + \text{aq.}$

	Calculated.	Found.				Mean.
$(\text{NH}_4)_2\Theta$	52	22.41	—	—	21.54	21.54
$2\text{C}_2\text{O}_3$	144	62.08	61.35	61.57	—	61.46
$\text{H}_2\Theta$	18	7.75	—	—	—	—
aq.	18	7.76	—	—	7.50	7.50
	232	100.00				

The formula usually given in text-books on chemistry (Gmelin, Watts, &c.) is—

that is, with one more molecule of water than I find to be the case. For this formula the calculated percentages would be—

$(\text{NH}_4)_2\Theta$	52	20.80
$2\text{C}_2\text{O}_3$	144	57.60
$\text{H}_2\Theta$	18	7.20
2aq.	36	14.40
	100.00	250

* Mean of four.

	Calculated.	Found.
K_2O	32.24	32.34
C_4O_6	49.28	—
5HO	18.48	—
	100.00	

Graham deduced this formula from the amount of carbonate of potassium left on ignition (47.45 per cent.).

‡ *Pogg. Ann.*, vol. xciii., p. 24 (*supra cit.*)

Anderson* says that the binoxalate of ammonium may be obtained by mixing equivalent quantities of chloride of ammonium and oxalic acid (regarded as monobasic, $\text{C}_2\text{O}_3, \text{HO} + 2\text{aq.} = 63$), and gives as the formula—

He determined the oxalic acid alone; and, from the data that he gives, it would appear that, instead of the binoxalate, he really obtained the quadroxalate mentioned below.

Percentage of C_2O_3		
In his salt.	In the acid-salt above.	In the hyper-salt below.
61.92	62.08	61.80

I found that, by adding a hot solution of 53.5 grms. (1 equiv.) chloride of ammonium (NH_4Cl) to a hot solution of 63 grms. ($\frac{1}{2}$ equiv.) of crystallised oxalic acid ($\text{C}_2\text{H}_2\text{O}_4, + 2\text{aq.}$), there were deposited, on cooling, crystals of the hyperacid salt of the formula—

	Found.						Mean.
	Calculated.	I.	II.	III.	IV.	V.	
(NH_4) ₂ O	52 11.16	11.12	11.29	—	—	—	11.29
C_2O_3	288 61.80	—	—	61.14	61.14	61.09	61.12
H_2O	54 11.59	—	—	—	—	—	—
2aq.	72 15.45	—	—	—	—	15.81	15.81
	466 100.00						

In these analyses, the ammonium was determined as chloroplatinate of ammonium, the oxalic acid by titration, and the water of crystallisation by drying at 100°C. until the weight remained constant.

Binoxalate of Sodium.

Anderson (*loc. cit.*) says that, by dissolving equivalent proportions of oxalic acid (equiv. = 63) and chloride of sodium (equiv. = 58.5) in hot water, crystals of this salt are obtained on cooling the solution. He gives the formula for the same:—

I found that crystals of the binoxalate were deposited from such a mixture, but that they answered to the commonly-received formula—

ON THE

POTASSIO-COBALTIC NITRITE KNOWN AS FISCHER'S SALT, AND SOME ANALOGOUS AND RELATED COMPOUNDS.

By SAMUEL P. SADTLER.

(Continued from p. 10.)

HAVING formed, from these analytical results, our conclusions, let us see if we can find any confirmation of them from other sources. Langt states that, although the corresponding soda and ammonia salts were probably formed, yet they could not be obtained on account of

their solubility. By using a strong NaNO_2 solution,* I succeeded in obtaining the new soda compounds which I am about to describe. To a solution of CoCl_2 , which had been boiled and then acidified with acetic acid, I added an excess of NaNO_2 solution. The mixture instantly became of a dark colour, and a yellowish-brown salt began to form, with brisk evolution of nitric oxide. After some hours, when the evolution of gas was progressing but slowly, I added some more of the NaNO_2 solution, testing, also, to assure myself that the solution was acid; and, in a little while, the solution began to assume a yellowish colour, and I found a clear, yellow salt depositing. This led to the conjecture that there were two distinct soda-salts. I accordingly sought to obtain them distinct, for analysis. This I found to be difficult. The brown salt I readily got almost pure, but succeeded only partially in obtaining the yellow one distinct. The brown salt continues to form, to a greater or less extent, even after the formation of the yellow one has begun. The preparations were all washed with acetate of soda, which was displaced with alcohol. From analyses of them, and from other and subsequent results, I am led to consider them as salts analogous to Fischer's salt, and differing from each other in the number of atoms of NaNO_2 in combination with the Co_2NO_2 . The brown salt I would call a *di-sodio-cobaltic-nitrite*, and the yellow one a *tri-sodio-cobaltic-nitrite*; giving them respectively the formulæ—

H_2O	2.18	—	—	—

Some error connected with the CaCl_2 tube, which I am entirely unable to account for, has here caused an error. It will be observed that in each case the total loss of the combustion-tube is very nearly what the theoretical per cent of $\text{H}_2\text{O} + \text{N}$ would demand, while the increase in the CaCl_2 tube is out of all proportion. If we examine the results in the yellow salt, we see that all these preparations are more or less mixtures. The last preparation, indeed, might be put equally under the head of the 2-atom salt, the per cent in brackets showing the per cent Na_2O calculated on the other formula. We are fortunately, however, not dependent solely on these analyses for our evidences of the existence of these two salts. On account of their partial solubility, we are enabled to obtain substitution-compounds from them, which throw very strong light on the composition of the alkali-cobaltic nitrites.

* The KNO_3 and NaNO_2 solutions used in this work were prepared as follows:—1 part of nitre and 2 parts of lead were fused together, after Stromeyer's well-known method. After the complete oxidation of the lead, the residue was boiled several times with water. The solution was then filtered, to remove the undissolved litharge. Into the filtrate (which contained more or less free alkali) the red gas evolved from nitric acid and sawdust was passed, until a neutral reaction was obtained. This red gas, however, does not consist of the oxides of nitrogen alone; it also contains some carbonic acid. This throws down, as carbonate of lead, the litharge which had gone into solution. It is now filtered, and the filtrate evaporated to an oily consistency, when the saltpetre in it will almost all crystallise out. We filter it again, and, if we wish it still purer, we can give it the treatment with alcohol described by Hampe (*Ann. Ch. u. Ph.*, 125, 335); this frees it completely from saltpetre, and concentrates it.

† The found percentages of $\text{N} + \text{H}_2\text{O}$ in the brown salt is the average of two determinations.

* *Qu. Journ. Chem. Soc.*, vol. i., 231 (1849).
† *Jr. Fr. Ch.*, lxxvii., 303.

In one case, after the formation and filtering-off of some of the brown salt, chloride of luteo-cobalt was added to the wine-coloured filtrate, which probably held some of both salts in solution. The strong tendency which luteo-cobalt possesses to form double salts suggested to Dr. Gibbs that some results might be here obtained. A beautiful, yellow, crystalline salt formed and settled quite readily. I then prepared a considerable amount of it, for analysis. It proved to be as good as insoluble in cold water; so that its washing was an easy matter. Its analysis shows very clearly that it was formed from the tri-sodio-cobaltic nitrite, or yellow soda-salt, which existed in the solution, and that 1 atom of luteo-cobalt exactly replaces the 3 of Na_2O , giving it the formula—

	Theor. p. cts.	Found p. cts.
Co_2O_3	32.87	33.04
NH_3	20.20	19.91
N_2O_3	45.15	44.50
H_2O	1.78	2.37

I now tried chloride of purpureo-cobalt upon some of the same solution, and got a roseo-cobalt compound exactly analogous to that of luteo-cobalt, its formula being $\text{Co}_2, 6\text{NO}_2 + \text{Co}_2, 10\text{NH}_3, 6\text{NO}_2 + \text{H}_2\text{O}$.

The following were the analytical results:—

	Theor. p. cts.	Found p. cts.
Co_2O_3	34.02	33.18

This salt is not nearly as insoluble, however, as the luteo-cobalt salt, and but little of it could be obtained. At first I got it as a yellow and very crystalline salt on the sides of the beaker, after standing some little time. The crystals, examined under the microscope, were beautifully-defined, monoclinic prisms, with terminal planes. The portion I analysed had more of the colour of the salts of roseo-cobalt, and showed, under the microscope, a star-shaped aggregation of small crystals.

I also formed, in the soda-salt solution, a yellowish xantho-cobalt compound, having probably an analogous constitution, but did not get enough of it to analyse. Examined under the microscope, the crystals were seen to be of a peculiar cup-shaped appearance, and quite large and pointed.

The ammonium-salts were next examined. That one, at least, existed had been found by Gibbs and Genth,* although it had not been analysed by them. Erdmann† had, however, formed an ammonium-salt exactly corresponding to Fischer's salt. I succeeded in forming this and another; the two exactly corresponding, in constitution, to the two soda-salts. The circumstances under which the different salts form I am not able, however, to state at all positively, except that, in forming the 3-atom salt, I had more concentrated CoCl_2 and NH_4NO_2 solution. They are both bright yellow, and could not be distinguished by their colour. We may term them the *di-ammonio-cobaltic nitrite* and the *tri-ammonio-cobaltic nitrite*, their formulæ being respectively—

	Theor. p. cts.	Found p. cts.
Co_2O_3	24.20	24.09

	Theor. p. cts.	Found p. cts.
Co_2O_3	20.39	20.55

Lang is more nearly right in the case of these ammonia-compounds than in regard to the soda-salts, they being much more soluble. I was unable, however, to obtain

any substitution-compounds. With this additional light, we are now prepared to draw some conclusions. We find that our luteo-cobalt and roseo-cobalt compounds are exactly analogous to the cobaltcyanides of luteo-cobalt and roseo-cobalt formed by Gibbs and Genth,* the only difference being that the monatomic radical NO_2 here replaces the monatomic radical Cy . This, I think, gives us a very strong argument in favour of the exact analogy of the 3-atom soda-salt (and, with it, of Fischer's salt) to the cobaltcyanide of potassium, from which the salts of Gibbs and Genth were formed. With this view of these salts, we are able to discern yet other analogies. Iridium forms a number of sesquioxide-salts, very similar to those of cobalt. We have, indeed, two double chlorides of iridium, exactly analogous to the 2-atom and 3-atom soda or ammonia salts. Their formulæ are— $\text{Ir}_2\text{Cl}_6 + 4\text{KCl}$ and $\text{Ir}_2\text{Cl}_6 + 6\text{KCl}$, in which we should expect monatomic Cl to be exactly replaceable by monatomic NO ; and so we find that it is. Dr. Gibbs has discovered an iridium-salt, having the formula, $\text{Ir}_2, 6\text{NO}_2 + 6(\text{KNO}_2) + 2\text{H}_2\text{O}$, an exact analogue of Fischer's salt. Lang† also has discovered a rhodium-salt, whose formula, $\text{Rh}_2, 6\text{NO}_2 + 6(\text{KNO}_2)$, is precisely analogous. If we place together, for a moment, the three salts in question, their identity of constitution becomes apparent.

Gibbs.

Lang.

Sadtler.

If, therefore, we are to place any dependence at all upon analogy, the universal occurrence of the hexatomic Co_2 atom in all our compounds is what we should expect *a priori*. The analyses of the series of salts, I think, fully confirms this expectation.

I have now to discuss some related compounds—those formed in neutral solutions. Erdmann first pointed out the distinction between these and the normal Fischer's salt. He obtained and analysed a yellow "neutral salt." I obtained one corresponding to this, and one of a different ratio. By adding a somewhat dilute solution of KNO_2 to a warm solution of CoCl_2 , I obtained a highly crystalline precipitate, which was shortly followed by a somewhat crystalline, greenish salt, which was again followed, after some time, by a yellowish precipitate with little or no crystalline character. The appearances were indicative of the successive formation of three protoxide-compounds. This, however, I found, was not the case. The black precipitate, under the microscope, was seen to consist of beautifully-defined cubes of a very dark green colour; and the green precipitate was seen to consist of similar cubes, though much smaller. Analysis afterward proved them to be the same salt in different states of aggregation. On adding a warm concentrated solution of KNO_2 , however, to a warm concentrated solution of CoCl_2 , nothing is formed but a flocculent yellow precipitate, which appears to be the same as that which I formed over mercury in the eudiometer-tube. The formulæ of these salts appear to be as follows:—For the black or green salt, $2(\text{Co}_2\text{NO}_2) + 2(\text{KNO}_2) + \text{H}_2\text{O}$; and, for the yellow salt, $\text{Co}_2\text{NO}_2 + 2(\text{KNO}_2) + \text{H}_2\text{O}$. And the first may be termed a *potassio-dicobaltous nitrite*, and the second a *potassio-monocobaltous nitrite*.

In looking over the analytical data of these analyses of protoxide-salts, we notice a striking similarity between the weights of salt taken and weights of double sulphates obtained. The explanation is very simple, and yet I believe there is involved in it a fact of importance. The similarity of weights is due to the similarity of atomic weights of N₂O₃ and SO₃ (76 and 80) with which the bases are combined. Now, in none of the very many determinations made in the "acid-salts" do we find such a similarity; on the contrary, we find the weight of double sulphates to be invariably less than the weight of salt taken, and in a fixed ratio. The explanation of this is that Co₂O₃·N₂O₃, by digestion with H₂SO₄, is converted into 2 atoms of neutral CoSO₄, and becomes 2(CoSO₄). 2CoO, 2N₂O₃ simply assumes SO₃, instead of N₂O₃, and becomes likewise 2(CoSO₄). The first loses an atom of NO₂, which the second does not. We have here a strong evidence of the totally different *habitus* of the Co atom in the "neutral" and in the "acid" salts.

(To be continued).

ON THE ANILINE OR COAL-TAR COLOURS.*

By W. H. PERKIN, F.R.S.

Coal-Tar, Benzol, Nitrobenzol, Aniline, and Aniline Purple or Mauve.

In this short course of lectures it is my desire to bring before you a somewhat condensed history of the artificial colouring matters, generally known as the "Coal-Tar Colours." By this designation it is not meant to imply that colouring matters actually exist in coal-tar, and may, therefore, be extracted from it, but that coal-tar is the source of certain products which, when changed by various chemical processes, are capable of yielding coloured derivatives. You will thus perceive that it is important for us to consider the various means employed to obtain the raw materials before giving our attention to the colouring matters themselves. We will, therefore, at once proceed to the consideration of "coal-tar;" its formation and constitution.

Coal-tar consists of the oily fluid formed by the destructive distillation of coal, and is obtained as a secondary product in the manufacture of coal-gas. Originally, coal-tar was a great nuisance to the gas manufacturer, and it was often a problem to him what he should do with it. I need scarcely say that this state of things is now changed. In the gas works the coal is distilled in large retorts, sometimes 25 or 30 feet in length. They are made of fire-clay or iron, and several are arranged in one furnace, or oven, as it is usually termed. Each retort is fitted with an iron mouth-piece, from which a vertical tube rises, the mouth-piece also having a door fastened with a cross-bar and screw.

When in use these retorts are rapidly filled with coal by means of a proper scoop, and then the doors luted and fixed so as to be air-tight. Distillation commences immediately, as the retorts are constantly kept red hot. The gas and other products which form pass up the front vertical pipe (connected with the mouth-piece), through a bend, and down into a long horizontal tube, called the "hydraulic main." Here most of the oily products condense, and as they accumulate pass on with the gas down the general main, and flow into a tank provided for their reception. These oily products constitute "coal-tar." The coal-gas, leaving this tar behind, passes on to the condensers, and deposits a second but smaller quantity of

tar, and is then purified and stored in the gas-holders. The gas, however, does not interest us now.

I am here distilling some coal in a small glass retort, the beak of which is inserted into one of the openings of a three-necked receiver. The second opening is connected with the tube, so that the gaseous products may be examined, whilst the third and lower one is fitted to a small bottle, in which you see we have already obtained a quantity of an oily fluid. This is our coal-tar.

Having now seen how coal-tar is produced, we will consider of what it consists. Coal-tar is by no means a definite body, but contains a great number of different substances, as a glance at the following table will show:—

TABLE I.—PRODUCTS OF THE DISTILLATION OF COAL.

* The Cantor lectures, delivered before the Society of Arts.

This list, however, does not indicate all the constituents of coal-tar, but only those which chemists have, up to the present time, succeeded in separating from it; moreover, when we consider how greatly coal differs in composition, and also that the products vary according to the temperature to which the coal has been submitted, it is evident that coal-tar must be an almost endless source of chemical products. Many would, perhaps, consider this list a perfectly hopeless jumble of names impossible to impress upon the memory; but, fortunately, chemists are able to classify their products, so that this formidable array of substances may be grouped under three or four different heads only, and, therefore, their relationship being once understood, little difficulty is experienced in remembering their names.

Amongst these products, and at the lower part of this table, you will observe a substance called "aniline." This substance is of great interest to us, being one of the principal sources of the coal-tar colours. Aniline was discovered by Unverdorben, in 1826, amongst the products of the distillation of indigo, and from its property of forming crystalline compounds with acids was called "crystalline." Afterwards Runge obtained it from the distillation of coal, and, because it gave a blue colouration with a solution of chloride of lime, called it "kyanol," or blue oil. Fritzsche, still later, obtained aniline by the distillation of indigo with hydrate of potassium, and gave it its present name, derived from *anil*, the Portuguese for indigo. About this time Zinin discovered a remarkable reaction, by which he obtained aniline from a substance called nitrobenzol; he called it, however, benzidam. The products obtained by these different chemists were not at first known to be identical; and it was not until Dr. Hofmann investigated the subject that they were all shown to be the same body, aniline.

Zinin's process for the conversion of nitrobenzol into aniline consisted in treating the nitrobenzol with an alcoholic solution of sulphide of ammonium; this was greatly improved upon by Bechamp, who employed a mixture of finely-divided iron and acetic acid, in place of sulphide of ammonium.

This is a brief sketch of the history of aniline up to the time of the discovery of the mauve dye; it was then purely a laboratory product, and was prepared in very small quantities at the time, and only when required for scientific research. Chemists have always been desirous of producing natural organic bodies artificially, and have in many instances been successful. It was while trying to solve one of these questions that I discovered the "mauve." I was endeavouring to convert an artificial base into the natural alkaloid quinine, but my experiment, instead of yielding the colourless quinine, gave a reddish powder. With a desire to understand this peculiar result, a different base of more simple construction was selected, viz., aniline, and in this case I obtained a perfectly black product; this was purified and dried, and when digested with spirits of wine gave the mauve dye.

You will perceive that this discovery did not in any way originate from a desire to produce a colouring matter, as is sometimes stated, but in experiments of a purely theoretical nature.

After showing this colouring matter to several friends, I was advised to consider the possibility of manufacturing it upon the large scale, and was eventually, induced to make the experiment, though, I must confess, not without considerable fear of the result, especially as my chemical advisers set before me anything but encouraging prospects.

Starting this manufacture, the first difficulty was to obtain the source from which aniline could be obtained at a sufficiently low price. It was at once evident that it was far too costly a product for this purpose.

Lang is more successful, therefore, directed to the extraction of compounds than in any other after very numerous experiments, much more soluble. Difficulty of purifying it was so great,

* "Researches on
+ *Jour. Pr. Ch.*, x

source left, namely, nitrobenzol; but to prepare aniline from this body necessitated the establishment of a new manufacture; nitrobenzol at that time not being a commercial article, and although it could be produced in small quantities without much difficulty, yet when tons were required at a limited cost many obstacles presented themselves.

Having spoken of nitrobenzol, it will be necessary, before proceeding further, to tell you something of the body it is prepared from, and also how it is made in quantity. Nitrobenzol is produced from a derivative of coal-tar called benzol—you will see it mentioned in the list of coal-tar products. It is composed exclusively of carbon and hydrogen, and is, therefore, called a hydrocarbon.

Benzol was discovered by Faraday, in 1825, one year before aniline by Unverdorben. Its existence in coal-tar was first pointed out by Dr. Hofmann, in 1845, and afterwards Mansfield showed that an almost unlimited supply might be obtained from this source. Benzol is a volatile oil, boiling at a temperature of 80·8°C., nearly 20° lower than water, and is also very inflammable, burning with a smoky flame. When ignited it cannot be extinguished by water, as it floats upon its surface. Its vapour, when mixed with air, is explosive. It is also very dense. This I can easily show you by decanting a small quantity of benzol vapour several times from one vessel into another, and then igniting it. Instances have been known, when distilling benzol in large quantities, and some leak in the apparatus has occurred, so that its vapour has escaped, that it has run along the ground, and been ignited by a furnace situated thirty or forty feet distant, and instantly run back to the apparatus. To illustrate this I will pour some benzol vapour into the top of a slightly inclined trough, fourteen feet long, at the lower end of which is placed a lamp. The vapour will be seen to run gradually down till it reaches the lamp, where it ignites and instantly rushes back to the top of the trough. One of the most remarkable properties of benzol is, that when cooled down to nearly the freezing point of water, it solidifies to a beautiful crystalline mass. This property of benzol is sometimes taken advantage of when it is required in a very pure state, as the impurities which accompany it are fluid, and do not freeze when cooled with ice.

Benzol is often sold under the name of benzine collas, for the purpose of removing grease from wearing apparel. But let us consider how benzol is separated from the great number of products with which it is associated in coal-tar. The first operation consists in distilling the coal-tar, just as it comes from the gas-works, in large stills, holding one or two thousand gallons each; these are often made of old steam-boilers; at first very volatile and light oily products come over, and are collected until their density increases to such an extent that they no longer float upon water. These constitute crude coal-tar naphtha. The distillation is then carried on, and heavy, or, as they are technically termed "dead," oils, are collected, a residue of common pitch being left in the still. This pitch is generally run out, and cast into blocks; but sometimes the distillation is carried on after the dead oils have been obtained, when a mixture of solid oily products distils, nothing but a kind of coke being left behind. These latter substances, however, do not interest us now.

The light oil, or crude coal-tar naphtha, is then purified by one or two alternate distillations with steam and treatments with concentrated sulphuric acid. It is thus rendered a colourless fluid. Thus purified, coal-tar naphtha contains, besides benzol, at least four or five other bodies. These, however, mostly differ from benzol in being less volatile; therefore, the naphtha is again distilled, the first, or more volatile, portions only being collected for benzol. By repeating this process of fractional distillation several times, commercial benzol is obtained. Some manufacturers employ stills of a peculiar construction, which enables them to obtain a good product

There was, therefore, but one

by a smaller number of distillations. Benzol, when treated with fuming nitric acid or aquafortis, undergoes a remarkable change. At first the two fluids mix and become of a dark brown colour and slightly warm, in the course of a few moments red fumes appear, and the mixture enters into ebullition. During this violent action the colour of the liquid becomes lighter and ultimately changes to orange. If water be now added to this product, the benzol, which is such a light body, will be seen to have completely changed into a dense yellow oil sinking in water. This oil is nitrobenzol. Nitrobenzol was discovered in 1834, by Mitscherlich. It solidifies into a crystalline mass at a temperature of about 3° C.; its odour is like that of the oil of bitter almonds, and before the introduction of coal-tar colours it was made in small quantities, and sold under the name of essence de Myrbane, for the purpose of scenting soap.

From the energy with which benzol is attacked by fuming nitric acid, nitrobenzol at first appeared to be a most difficult product to manufacture on the large scale, and this difficulty seemed the greater when it was found necessary that it should be made at a moderate cost. Moreover, at the time I am now referring to, fuming nitric acid, sp. gr. 1.5, could not be obtained in the market, or only at such a cost as almost to preclude its use. Under these circumstances, two mixtures were experimented with instead of the nitric acid in a very concentrated condition. The first was a mixture of nitrate of sodium and sulphuric acid, the second a mixture of ordinary nitric acid, sp. gr. 1.3, and sulphuric acid. The mixture of sulphuric acid and nitrate of sodium was preferred, and employed on the large scale.

(To be continued.)

NOTICES OF BOOKS.

On the Manufacture of Beet-Root Sugar in England and Ireland. By WILLIAM CROOKES, F.R.S., &c. Illustrated with Ten Engravings. London: Longmans, Green, and Co. 1870.

WHILE we cannot, for obvious reasons, pronounce an opinion on the merits or demerits of this book, we may perhaps be allowed to say that the author's aim has been to give, in a convenient-sized volume, all the information and statistics necessary for the culture of the beet and the establishment of beet-sugar manufactories.

The subjects treated of are:—The Culture of the Beet; Technology of the Beet-Sugar Manufacture; the Chemistry of Beet-Root Sugar, Juice and Molasses; Filtration and Concentration of the Juice; Decolourising the Syrup; Water Supply; the Concreting Process; the Utilisation of the Spent Beet-Root Pulp; the Manufacture of Spirit from Beet-Juice; the Suckrate of Lime Process; Manufacture of Potash Salts; Excise Regulations; Percentage of Sugar in Different Kinds of Beet; Yield per Acre; Description of Dr. C. Schiebler's Calcmeter, or Apparatus for the Quantitative Estimation of the Carbonate of Lime in Bone-Black by Volumetrical Assay.

It is certainly a cause for astonishment that a country ranking high in agriculture, and highest in everything relating to manufacturing appliances, should have hitherto kept far behind Continental agriculturists in the successful prosecution of this industry; a fact the more to be wondered at since the spent beet-root pulp is even a better food for cattle than the root crops so extensively cultivated for that purpose. Excepting the central and northern parts of Scotland, and the high moor-grounds, the United Kingdom is as favourably situated for the cultivation of the sugar-beet as any portion of the European Continent; whilst the higher standard of agricultural efficiency in this country would greatly tend to secure good crops with existing systems of rotation. That agricultural labourers can be readily taught the routine of the

manufacture is evidenced by Continental experience; and the skilled supervision does not require more than, at the utmost, half a dozen men.

The Chancellor of the Exchequer, in his recent speech on the Budget, when introducing the subject of the partial remission of the sugar duties, said:—"We know that the beet-root industry of the Continent seems to have got over its difficulties, and to be spreading very widely. There is also the prospect of the growth of beet-root, with this object, in our own country; and, if we could hope for anything so good as that it should be introduced with success into the south of Ireland, it would be one of the greatest blessings that could possibly befall that country." The sugar-beet has been grown experimentally in various parts of the county of Kilkenny, by the Hon. L. Agar Ellis, M.P.; and the important result has been established that the climate of the south-east of Ireland is suitable for the growth of such a crop, and that sugar-beet can there be grown of a quality which will remunerate the manufacturer. It is calculated that a proportion of 8.5 of crystallisable sugar will pay; and, in some instances, comprised within the range of the experiments, there was a yield of 10.91 and of 8.94. Mr. Ellis observes that, to make the crop worth growing, either the present sugar-refiners of Ireland must put up machinery for "converting" it, or separate districts must erect the necessary works. That the magnitude of the industry is sufficient to warrant operations on the largest scale is shown by the fact that last year France alone produced no less than 300,000 tons of beet-sugar, which, at £25 per ton, would be worth £7,500,000, the molasses (100,000 tons at £5) bringing up the value to £8,000,000. Beet-root may yet redress the injury inflicted on Ireland by the potato.

As some remarks were recently made in our journal respecting Dr. Schiebler's calcimeter, we propose, in our next number, to give a full description of the instrument, together with the woodcut as it appears in the above work.

Abridgments of Specifications Relating to Aëronautics. A.D. 1815—1866. London: Messrs. Spottiswoode. 1869.

WITH indefatigable zeal the gentlemen who are the active workers under the Commissioners of Patents proceed in the laudable work of compiling and publishing the series of useful works, of which the above is the forty-first already issued for public use.

The little volume before us is especially interesting, because the introduction contains the history of aëronautics, set forth in a lucid and clear manner, so as to show the connecting-links that bind together the history of this subject.

After referring to the ideas expressed in the fables of the Ancients, and the accounts of Icarus and Dædalus, to show that mankind always had in view the possibility of elevating themselves in the air, the author says:—"The term aëronautics is rather in advance of the condition of the subject at the present day, since no means are known by which a heavy body may be elevated into the air, and navigated as a ship is on the sea. The utmost that has been done is to take advantage of the different aerial currents that exist at a given time at various elevations, and, by raising and lowering a gas-balloon accordingly, to approximate to the desired direction. The various methods (many proposed, and a few realised) that have the accomplishment of aerial navigation for their object may be classified thus:—Kites; fire-balloons; hydrogen-balloons; coal-gas balloons; mechanical apparatus."

The author next briefly alludes to the history of each of the matters just specified, calling attention to the very great antiquity of the use of kites for amusement among the Chinese and Japanese; and explains the term fire-balloons from the well-known fact that the ascent of these balloons is due to the rarefaction of the air caused by

the fire which is kept burning beneath them. This is effected usually by a sponge dipped in strong spirits of wine. This mode of letting up balloons, having become rather a general amusement on some parts of the Continent, was forbidden by the authorities, on the ground that the falling-down of these fire-balloons (which often became ignited, and burst into flames) gave rise to fires, especially in country districts. The mechanical means of flight is at present only represented by a toy called the "aërial top," which has light, but strong, blades attached, at a certain acute angle, to its axis.

We next meet with a brief chronological summary of the history of this subject, beginning with Archytas (400 B.C.), who constructed a wooden pigeon which could fly by mechanical means, up to our day, relating Mr. J. Glaisher's researches. This summary aims at the registration of scientific data, not a collection of ascents; and is, therefore, of very great value. Attention is drawn to the very complete series of works on aeronautics, accessible to the public, at the Patent Office Library; and, among these, to a most valuable manuscript work, entitled, "Aëronautica Illustrata," an extensive and valuable collection of writings, illustrations, and original documents that have been collected and arranged in the course of years.

Space forbids us to enter into more particulars; but the compiler and the author of the introduction to this neat little volume deserve great credit for their work. And, since the price (sixty pages) is only 4d., we abstain from further details, but recommend the volume, not only for amusing, but also for instructive, reading.

CORRESPONDENCE.

ERECTING PRISM.

To the Editor of the Chemical News.

SIR,—Referring to Mr. Browning's reclamation in the CHEMICAL NEWS, vol. xxi., p. 264, in which he mentions that he made one of these prisms "two or three years since," allow me to mention that a full account of the arrangement (in fact, the article published in the CHEMICAL NEWS, vol. xxi., p. 246), appeared in the *Journal of the Franklin Institute*, for June, 1867.

The prism had been exhibited at the meeting of the Institute in the previous month and was made some time before,* so that, taking the earliest of Mr. Browning's dates, this is another of those remarkable instances of coincidence in ideas regardless of distance which are so often met with.

HENRY MORTON.

MISCELLANEOUS.

University of London (D.Sc. Examination).—Branch I. (*Mathematics*).—John Hopkinson, Trinity Coll., Camb., and Owen's. Branch IV. (*Inorganic and Organic Chemistry or Mineralogy*).—James Bottomley, B.A., Owen's College; David Watson, Royal School of Mines; John Watts, private study. Branch V. (*Organic and Inorganic Chemistry*).—James Campbell Brown, Royal College of Chemistry and private study; Charles Romley Alder Wright, Owen's College. Branch VIII. (*Physical Optics, Heat, Acoustics*).—John Hopkinson, Trinity Coll., Camb., and Owen's.

Royal School of Mines.—After a meeting of the Council, held on Saturday, the 2nd inst., the results of the

examinations for the year were announced as follows:—*Third Year's Students*—Associates in Mining, Messrs. W. Gowland, Archibald Liversidge, and H. J. Renwick; in Metallurgy, W. Gowland, Dillon, Liversidge, W. W. Bickerton, F. W. Bailey, and T. Jones; in Geology, W. Johnson Sollas. Medals—De la Beche Medal and Prize of Books to W. Gowland. *Second Year's Students*—H.R.H. Duke of Cornwall's Scholarship of £30 for two years, to P. C. Gilchrist; Royal Scholarship, £25, for one year, to R. R. Atkinson; Sir Roderick Murchison's Medal and Prize of Books, to P. C. Gilchrist. *First Year's Student*—Royal Scholarship of £15, for one year to (1.) W. H. Greenwood, and (2.) F. C. Mitford.

The Franklin Institute.—At a recent meeting of this Institute, Professor Morton resigned the office of Resident Secretary, he having accepted an appointment in a distant city. The resignation was accepted, and the President stated that Professor Morton had consented to continue his charge of the *Journal of the Franklin Institute*, which had achieved so desirable a position under his management. The new position accepted by Professor Morton is that of President of a College of Mechanical Engineering, to be established in Hoboken, opposite New York. He is succeeded at the Institute by Dr. W. H. Wahl.

Magic-Lantern Pictures on Gelatine by a New Method.*—At the last meeting of the Franklin Institute, the Resident Secretary, Professor Morton, exhibited in the lantern some pictures on gelatine, prepared in a manner devised by Mr. Sheperd Holman, a member of the Institute. For this purpose a sheet of gelatine, such as is used for tracing by engravers, was securely fixed over an engraving, and with a sharp steel point (made by grinding down the end of a small round file), the lines of the original traced pretty deeply on the transparent substance. Lead-pencil or crayon dust was then lightly rubbed in with the finger, and the picture was at once ready for use. A number of such drawings could be easily carried between the leaves of a book, each in succession being held in a frame or cell made of two plates of glass separated by a frame of thin card or three edges, and united by paper or muslin pasted around the same edges. The effect of these drawings in the lantern was excellent, and their ease of production very great.—*Journal of the Franklin Institute*.

A New Artificial Light.—The *Berggeist* describes a new artificial light which has recently been successfully experimented with. It is the Philipp carbo-oxygen lamp, and its trial during the month of March, at Cologne, was such as to win approval on every hand. The system of lighting is distinguished from those already in existence by its simplicity, its brilliancy, and, moreover, by its less noxious character. The light is generated by the simultaneous combustion of a liquid chemical compound and a current of oxygen, arrangements for the purpose being constructed in a suitable lamp. The gas is derived from the atmosphere either by chemical or mechanical means; the chemical methods being to act upon the oxygen of the air with chloride of copper (Mallett's method), or with manganate of potash (Tessie du Mothay's method), while the mechanical mode is that of utilising the different degrees of solubility of nitrogen and oxygen in water or other liquids. By compressing atmospheric air into receivers filled with water, a portion of the nitrogen is taken up by the water, while the oxygen remains insoluble in the water; the air, thus containing a goodly proportion of oxygen, is forced into a second reservoir of water, where a further amount of nitrogen is absorbed, and after the operation has been repeated seven or eight times, an atmosphere is obtained containing 97 per cent of oxygen. The nitrogen which has been separated is made use of in a well-constructed apparatus, as an auxiliary to the motive force. Experiments have established the fact that a flame fed with air containing 53 per cent of oxygen

* The charges against me on Mr. Zentmayer's books for the prism then used being dated March, 1867, while a smaller one, not charged, was made some months before.

* Communicated by Professor Morton.

yields a light equal in brilliancy to that obtained with pure oxygen, and with diluted oxygen of this kind the Philipp flame has a brilliancy of 90 to 100 candles, or ten times that of an ordinary gas jet. The light is of a bluish white, resembling very much that of electricity and magnesium. The liquid employed consists of liquid hydrocarbons, very rich in carbon; it costs but little, burns economically, and can be employed only in this particular direction. The combustion is maintained in a lamp—Philipp's carbo-oxygen lamp—fitted with a wick, into the flame of which the oxygen penetrates in a horizontal direction. The flame is thus made to assume the form of a star, and any heating of the wick-holder thereby prevented; if of the size and power above mentioned, the quantity of gas consumed is $5\frac{1}{2}$ cubic feet per hour. As to the lamp, no special attention is necessary beyond that of filling it with liquid, as the wick is of a very durable nature, and needs no trimming. The hydro-carbon employed is patented both in Europe and in America. This method of lighting is, we believe, likely to be adopted very widely. Independently of its simplicity and reasonable cost, which are, indeed, extreme, it possesses the very eminent and valuable qualifications of perfect security; no explosion is in any way possible, such as not unfrequently occurs with ordinary coal gas and with hydrogen. The costly trials undertaken by Tessie du Mothay, inaugurated at the exhibition of 1866, made a profound sensation at the time, and were regarded with considerable favour, although the apparatus employed was of a very costly description, and it was necessary to employ for the purpose two gases exceedingly dangerous to manipulate, which were brought through a double series of tubes, the one for ordinary gas, and the other for oxygen; the apparatus itself, moreover, necessitated a careful and continued superintendence. All these inconveniences disappear with the new carbo-oxygen system, which, besides its application to industrial purposes—the navy, railways, military operations, &c.—will be wonderfully well suited to photographic purposes, as has, indeed, been proved by the attainment of some very remarkable results. The *Bergeist* concludes by saying that a method of lighting endowed with such important qualifications as the lamp invented by M. Philipp cannot remain long before being extensively known throughout the world.—*The Photographic News*.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "*Jahresberichte*."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, June 20, 1870.

Omitting papers more strictly bearing upon mathematical, natural history, and mechanical subjects, this number contains the following papers and memoirs relating to physico-chemical science:—

Variations of Temperature Produced by the Mixing of Two Different Liquids.—M. Jamin.

Observations and Remarks on this Memoir.—J. Bussy.—The contents of these papers are chiefly speculative; and, as regards the latter paper, the author points out several discrepancies which exist between the results obtained by his experiments on this subject, and those of the first-named author.

Electric Effects Produced by the Contact of Non-Oxidisable Metals with Acids, Neutral and Saturated Saline Solutions, and on Capillary Affinity.—Prof. Becquerel.—In this paper, only published in abstract, the author describes the electric phenomena

observed when pure gold and platinum are immersed in various acids, ammonia, and neutral saline solutions, which do not exercise any action at all upon the metals alluded to. The main conclusion arrived at by the author is, that the state of the surface of the metals has great influence, and that, consequently, capillary affinity plays a very important part in the production of the electric phenomena (very feeble currents) produced.

Reversal of the Two Lines of Sodium in the Spectrum of the Light Produced by one of the Protuberances of the Sun.—G. Rayet.—Illustrated with diagrams.

Estimation of the Absolute Value of the Intensity of the Terrestrial Magnetism.—A. Cornu and J. Baillie.

Experimental Researches on the Length of Duration of the Electric Spark.—MM. Lucas and Cazin.—The authors employ two transparent discs placed upon the same axis. One of these discs is a fixture, while a more or less rapid rotatory motion can be imparted to the other. Upon both discs are painted the same number of opaque stripes, in the direction of the radius. When, therefore, an electric spark is observed through these discs, a certain amount of speed having been imparted to the movable one (the apparatus being placed in a darkened room), it is clear that, by the light emitted by the spark, a certain number of coincidences of the movable and fixed stripes may be observed, and these coincidences may serve to calculate the period of duration of the spark.

Precipitation of Muddy Matter from Water by the Aid of Dilute Saline Solutions.—Dr. Ch. Schlesing.—The author states that water, otherwise pure, but contaminated simply with clay (as may be the case with the water of rivers after heavy rain or fall of snow), becomes at once clarified by very minute quantities of some salts of lime. 1-1000th part of chloride of calcium for 1 part of water effects this purpose in a moment; the nitrate, bicarbonate, and caustic lime act in the same manner. The precipitated substance may be readily separated from the water by filtration, whereas the filtration of the water containing the suspended matter is very difficult, because the pores of the filters are choked. The practical importance of this matter is very great, since it is, for instance, a well-known fact that the water of some rivers (the Durance being notorious in this respect) does not, in winter time, and after heavy rainfall or snow-storms, become quite clear, even if left at rest in large ponds for a considerable time. The same is the case with the water of the Rhine, which, in its lower course, is often quite turbid for weeks together, simply from the effects of very finely-divided clay being kept suspended, even after the water has been at rest in tanks. The water of the river Durance supplies Marseilles with fresh water, the latter being brought to that city by a magnificent series of works, among which the celebrated Aqueduc de Roquefavour. The use of chloride of calcium is, however good, not indispensable; and our readers may be reminded here that the late Prof. Johnston, of Durham University, has very ably and fully explained the clearing of muddy, and thereby non-potable, water in his work, "*Chemistry of Common Life*," wherein he has also made reference to the use of certain bitter vegetable substances which have been applied, both in Egypt and in India, for the purpose of rendering the waters of the Nile, Ganges, Indus, and other large rivers, potable, many centuries before the rationale of the action of these substances was understood.

Law of Freezing-Points of Saline Solutions.—Dr. Güldberg.—An algebraico-physico-chemical essay.

Composition of Crude Soda; and on the Loss of Sodium resulting from its Manufacture according to Le Blanc's Process.—A. Scheurer-Kestner.—Although we reserve this highly-important paper bearing upon the manufacture of soda for full translation at a future date, we here quote that, while it is a well-known fact that, in practice on the large scale, a loss of from 15–20 per cent from the theoretical yield is experienced, the author has ascertained that the main cause of this loss (some of these causes are well known already) is the formation of insoluble (in water) sodic combinations, which remain in the lixiviated refuse. Volatilisation of sodium does not take place appreciably.

Rapid and New Method of Quantitative Estimation of Ammoniacal Salts; on the Causes which Prevent the Existence of these Salts in the Human Organism in other than Infinitesimally-Small Quantity.—Dr. Rabuteau.—The author prepares a solution of eau de Javelle (chlorure de soude, strictly a more or less pure hypochlorite of soda), by mixing, with a solution of 1 part of bleaching powder (hypochlorite of lime), a solution of 2 parts of carbonate of soda. The solution so obtained, containing, besides, excess of carbonate of soda, or free soda, is applied for the decomposition of the ammoniacal salts, so that nitrogen is set free. The remainder of the contents of this paper is strictly physiological, and the intention, as regards the application of the test liquid, is for the use of physicians in practice more than for the chemist.

Tribromhydrines.—Dr. Berthelot.—A lengthy memoir containing a series of critical remarks and observations on the last paper on this subject, by Dr. Henry, published in this periodical.

Preparation of Dibromated Ethylen.—Dr. Fontaine.—After referring, at great length, to the labours of several experimenters on this subject, and pointing out the incompleteness of their modes of preparation of the body alluded to, the author states that dibromated ethylen may be obtained without any evolution of gas, by pouring into bromated bromide of ethylen, $C_2H_3Br_2$, kept well cooled, an alcoholic solution of caustic potassa, care being taken to avoid any increase of temperature. As soon as the liquid has become thoroughly alkaline, water is added, and the dibromated ethylen separated by decantation.

On an Aromatic Glycol.—E. Grimaux.—The author of this long

paper describes the reactions by means of which he has succeeded in obtaining the tollylic-glycol—

This body fuses at about 113°; is very soluble in water, alcohol, and ether; and crystallises in needles. Heated with hydrochloric acid, it is converted into chloride of tollylen.

Dust- and Blood-Rains.—H. Tarry.—A very lengthy and interesting memoir on this subject, proving the true origin of these phenomena.

Notes relating to the Magnetic Perturbations observed by De Saussure while Sojourning on the Col du Géant, which Perturbations preceded the Terrible Hail- and Thunder-Storms which occurred during the year 1788.—C. Dufour.—The Col du Géant, at 3420 metres above sea level, is a portion of the Alps. The author of this paper calls attention to the relation which appears to have existed, but was not (as far, at least, as his own records prove) observed or noticed by the late De Saussure, between the severe perturbations of the magnetical instruments he had with him at the locality alluded to, and the exceedingly severe hail- and thunder-storm which followed the very next day (July 13th, 1788) of these perturbations, over a large portion of Europe, from the north of Spain to the Baltic. The author of this paper calls attention to these old observations (the Aurora Borealis was also seen faintly at the Col du Géant at the time); because, as noticed this year, the phenomenon last alluded to was immediately followed by several *bourrasques* bursting over Europe. By *bourrasques* are meant severe perturbations of the air, often accompanied by hail, thunder, heavy rains, and always high wind, if not, in some localities, hurricane.

June 27, 1870.

This number contains the following memoirs and papers bearing upon chemistry and collateral sciences:—

Observations and Remarks on M. Jamin's Paper "On the Variations of Temperature Produced by the Mixture of Two Liquids."—H. Sainte-Claire Deville.—The author, pursuing his course of combating hypothesis, attacks, in this paper, several of the statements made by M. Jamin, and especially points out the perfect uselessness of the idea of an absolute zero to explain the phenomena relating to the specific heat and free calorific.

Researches on some New Derivatives from Triethyl-Phosphine.—A. Cahours and H. Gal.—After referring to their former researches on this subject, the authors describe several new compounds of triethyl-phosphine and chloride of platinum, among which we notice a body composed according to the formula, $[Ph(C_2H_5)_3]_2PtCl$, a prismatically-crystallised, colourless substance, corresponding to Reiset's salt, $(NH_4)_2PtCl$. The triethyl-phosphine compound alluded to is decomposed at 100°, losing one equivalent of triethyl-phosphine. The authors have also produced compounds of the chlorides of gold and palladium with triethyl-phosphine, which, according to their researches, act towards the chlorides alluded to in a manner akin to the behaviour of ammonia with these chlorides.

Galvanical Deposition of Nickel.—H. Bouillet.—The author states that the assertion of M. Adams, in reference to the necessity of having the nickel solution absolutely free from alkalis and alkaline earths, is quite incorrect; and, in proof thereof, the author exhibits a perfectly coherent piece of nickel, obtained by Professor Jacobi, of St. Petersburg, from the double sulphate of nickel and magnesia, by the use of a nickel anode, which, curiously enough, is not entirely dissolved, but converted into a spongy suboxide of nickel.

Direction of Induction Currents obtained by the aid of Electrical Discharges.—J. Chautard.

New and Generally-Applicable Method for the Preparation of Organic Chloro-Bromated Compounds.—L. Henry.—The author states that, having read of Dr. Friedel's researches on the preparation of chlorobromides of the biatomic hydrocarbons, he has made some experiments with the chloro-iodide of ethylene, $(C_2H_4)ICl$, and with the chloro-iodohydrine of allyl, $(C_3H_5)(HO)ICl$, which, by the action of bromine, are converted into chloro-bromated compounds. The author continues his researches on this subject.

Silico-Propionic Acid.—C. Friedel and A. Ladenburg.—While organic chemistry is aptly called (say the authors) the chemistry of carbon, we are engaged in researches which tend to place silicon parallel to the former element. What is called silico-propionic acid, $SiC_3H_5O_2$, is a compound wherein a large percentage of the carbon of propionic acid is replaced by silicon. The physical aspect, and many of the properties of this body, are akin to silica; but it is a combustible substance, insoluble in water, but soluble in a hot and concentrated solution of caustic potassa. M. Dumas observed, during the meeting, at which this paper was read, that it is not impossible that there exist in nature organic compounds of silica, a remark which gave rise to the following paper:—

Observations on Dr. Friedel's Memoir.—P. Thenard.—The author begins with stating that M. Dumas is quite right, and relates, further, that he (M. Thenard) is at present engaged on researches of organic acids which contain even 24 per cent of silica entirely disguised. When ulmic acid is treated by ammonia, azhumic acid is formed; this contains nitrogen so fixed, that it is only eliminated at a temperature of about 1200°. This acid is possessed of the remarkable property of readily dissolving silica and combining therewith, in the same manner as the compound alluded to above by Dr. Friedel. The author also states that, although his researches on this subject are not yet quite concluded, he is justified in stating that all arable and garden soil, and, far more so, farm-yard manure, contain similar organic

siliceous compounds, which play an important part in the feeding of the plants.

Phospho-Platinic Compounds.—P. Schützenberger.—Mainly a collection of lengthy formulae.

Existence of Organic Remains in Rocks supposed to be of Igneous Origin.—C. Montagna.—The author replies to the critical remarks made by several German and Russian geologists on his theory of the formation of the so-called igneous rocks, about which he published some papers a couple of years ago. He says that the fossils discovered by him, and deposited in his collection at Naples, are not microscopic objects, but so large as to attract even the attention of the wayfarer people who happen to pass by the spot (near Naples) where they are found.

Electric Condensation.—M. Neyreneuf.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 4, 1870.

The only paper relating to the physico-chemical sciences in this number is—

Superficial Viscosity of Thin Sheets of Saponine Solution.—C. Van der Mensbrugghe.—The author describes, and illustrates by a cut, an experiment wherein the electrical repulsion aids the superficial viscosity of a solution of saponine to keep an open space between the thin sheet of that substance, notwithstanding the tendency of the capillary action to close that opening.

Annales de Chimie et de Physique, May, 1870.

This number contains the following original memoirs and papers:—

On Collision.—A. Dupré.—A very exhaustive and lengthy mechanico-mathematical paper.

Researches on the Gaseous Products of the Combustion of Coal.—A. Scheurer-Kestner.—We regret that, owing to the absolute necessity of the woodcuts added to this paper for understanding its contents, we cannot enter into details on this scientifically as well as practically-interesting subject. The author's experiments confirm those made, now many years since, at Elswick (near Newcastle-on-Tyne), by Sir William Armstrong, Mr. J. A. Longridge, and the late Dr. T. Richardson, as far as regards the combustion of fuel without smoke also having the effect of eliminating from the chimney-gases those which are combustible.

Influence Exercised by Magnetism on Electric Jets Propagated in Partially-Vacuous Space.—A. De la Rive.

Polytechnisches Journal von Dingler, second number for May, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Changes Coal undergoes by Exposure to Air.—Dr. T. Richters.—The concluding part of this very lengthy paper; this portion treats on the so-called weathering of coals. The author has added to this excellent paper a review in tabulated shape, containing the results of analysis (quantitative estimation of carbon, hydrogen, oxygen, nitrogen, ash, coke, heating effect, and specific gravity) of various kinds of coals freshly taken from the pit, and after variable periods of exposure to air.

Lime and Cement.—W. Wolters. This paper treats mainly on the causes of the so-called binding and hardening of what is generally known as mortar, viz., the mixture of sand, water, and slaked-lime; the paper is divided into the following sections:—Slaking of lime; the binding; behaviour towards carbonic acid; gypsum (plaster of Paris); and sulphate of potassa.

Tin which has been Exposed to a Great Degree of Cold at St. Petersburg.—P. Lewald.—The author referring to the phenomenon first observed by Dr. Fritzsche, says, it is not at all a correct statement that the blocks of tin exposed to a cold of -35° should alter their state of aggregation from that cause; the real cause is that the blocks of tin, usually of 250 cubic inches capacity, are cast in iron moulds and, as a consequence thereof, the metal (tin) contracts unequally and so as to leave in the inside of the blocks cavities often so large as to occupy 40 cubic inches; these hollows are lined by a crystallised metal at a high degree of tension. The tin at St. Petersburg was laying heaped block upon block, and the effect of the cold was simply a remote cause to what took place, the weight of the blocks of metal placed on each other being such as to produce necessarily a pressure too great to be borne by the undermost blocks. The author says, if tin is molten and allowed to cool, so as to shrink uniformly, no cold, even of 40° or less, will have the effect observed in the locality alluded to.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk, April, 1870.

This number contains the following original papers:—

Mineral Springs met with in the Neighbourhood of Chur (Switzerland).—Dr. A. Husemann.—Some parts of the Helvetic Republic, and especially the Canton des Grisons, abound with valuable mineral-water springs. The springs of Passug, discovered in 1863

the water of the most prominent of these springs was analysed by Dr. A. von Planta-Reichenau. The locality where these springs are found is about 830 metres above sea level. The result of the analysis of the most important of the springs (Uricus spring) is:—Temperature of water, 8.1 (the temperature of the air being 4.4 at the time of observation); sp. gr. 1.007. 1000 parts of the water contain:—Chloride of sodium, 0.8493; iodide of sodium, 0.0008; sulphate of potassa, 0.1568; sulphate of soda, 0.0862; carbonate of soda, 3.7879; carbonate of lime, 0.7126; carbonate of magnesia, 0.3786; carbonate of protoxide of iron, 0.0202; phosphate of alumina, 0.0074; silica, 0.0100; traces of manganese, lithia, and strontia; free carbonic acid, 1.8082. The Theophilus spring, saline chalybeate, contains, in 1000 parts:—Solid and gaseous matter, 5.9524. The Fortunatus spring, a saline water very akin to that of the Uricus spring, contains, in 1000 parts:—Fixed and gaseous matter, 8.5391. The author describes further, at length, the Belvedra springs and the Castil springs; the water of the former is saline-chalybeate; that of the latter, alkaline-chalybeate, and its composition very closely resembles the well-known Selters water from Nieder-Selters in the Province of Nassau (Prussia).

Purification of the Hydrate of Chloral.—F. A. Flückiger.—The main gist of this paper is that, for medicinal use, the re-crystallised hydrate of chloral alone is suited, while the author recommends, as the best solvent from which to obtain the hydrate in crystalline state, purified sulphide of carbon, the last traces of which are removed from the crystals by a moderately-strong current of cold air.

Experiments on the Production of Sulphuric Acid from Gypsum.—H. Reinsch.—A quintal (hundredweight) of gypsum, $\text{CaSO}_4 \cdot 2\text{H}_2\text{O}$, contains about 57 lbs. of sulphuric acid (so-called English). The author, after referring to the very many hitherto unsuccessful attempts made to obtain this acid from this most abundantly-found mineral, states that, when he mixed 2 parts of pulverised gypsum with 1 part of carbonate of ammonia, and poured water over this mixture, complete decomposition of the gypsum ensues, sulphate of ammonia is formed, and carbonate of lime. The sulphate of ammonia is, in its turn, decomposed by means of common salt, the result being the formation of sulphate of soda and chloride of ammonium, which can again be converted into carbonate of ammonia by means of chalk.

New Researches on Calisaya Bark from Java.—J. B. C. Moens.—The author communicates the results of his researches of ten species of *Calisaya dubia*, and two of *Calisaya vera*. The freshly-cut bark contains 64 per cent of water, and when air-dried about 73 per cent. The quantity per cent of all alkaloids together in the ten first-named species varies from 2.465 to 6.010. The quinine varies in quantity from 0.589 to 2.831 per cent. The cinchonidine (not met with in all the barks) is present in quantities from 0.539 to 2.41; the quantity of cinchonine varies from 1.405 to 3.909 per cent. The barks of *Calisaya vera* contained, respectively, 7.442 and 7.482 per cent of alkaloids; the quinine amounted to 3.670 per cent, and the cinchonine to 2.812 per cent. The barks alluded to contain, on an average, after having been dried at 125°, 2.332 per cent of ash, of which 0.728 per cent is lime.

Zeitschrift für Chemie von Beilstein, No. 10, 1870.

The number opens with—

Die Königlich Rheinisch-Westphälische Polytechnische Schule zu Aachen (that is to say—A Full Programme of the Royal Rheinisch-Westphalian Polytechnic School at Aix-la-Chapelle).—This establishment, to be opened on the 10th of October next is, says the programme, intended to be a technical high school of the same kind as the Polytechnic School at Hanover, the Architectural Academy and Technical School at Berlin, and a combination of the Ecole Polytechnique, Ecole des Mines, and Ecole Centrale des Arts et des Manufactures at Paris. The main subjects of ordinary instruction are fifty-eight in number, and, beside this, lectures on thirteen extraordinary subjects will be given; in fact, as might be expected from the Prussian Government, the establishment is in every respect complete. The building is an imposing and beautiful one, of large dimensions, fitted up with all the requisites for this purpose. It has been erected in a city, the best which could be selected in Rheinish Prussia, since it is readily accessible, and its situation is healthy; and, what is of more importance, it is eminently the centre of a large manufacturing, mining, and, technically, highly-developed district, and at an easy distance as well from the Rhine as from Belgium and France. The fees for students are exceedingly moderate, and the appointed teachers are men of experience, as well as high scientific standing. French is freely spoken among the middle and upper classes of the city alluded to, which is too well known for its beautiful environs to need further comment.

The following original papers are found in this number:—

Thihydrobenzoic and Dithiobenzoic Acid.—H. Hübner and J. Upmann.—The authors state that their object is to relate the results of their labours on thihydro acids in general, and the substances named at the heading more especially. They first enter into a lengthy discussion, which turns upon the correctness or incorrectness of the labours of Drs. Carius, Vogt, Engelhardt, and others on this subject, and next state, at great length, the preparation of chloro-salicylic acid, with the view of obtaining, from that body, thihydrobenzoic acid; but, since this did not lead to any good result, the thihydrobenzoic acid was prepared by placing dry benzoic acid in the receiver attached to a retort wherein fuming sulphuric acid was heated. The vapours given off converted the benzoic acid into a tough, pasty, brown-coloured fluid, which was first heated by itself, and next treated with carbonate of lead, yielding a salt, $\text{C}_6\text{H}_4\text{SO}_2 \cdot \text{O} \cdot \text{CO} \cdot \text{O} \cdot \text{Pb}$. This was converted into

a soda-salt, which, in its turn, was acted upon by chloride of phosphorus, yielding $\text{C}_6\text{H}_4\text{SO}_2 \cdot \text{ClCO} \cdot \text{Cl}$, sulphobenzoic acid-chloride, a fluid insoluble in water. This body, treated with tin and hydrochloric acid, yields, after purifying, $\text{C}_6\text{H}_4\text{SH} \cdot \text{COOH}$, thihydrobenzoic acid, very difficultly soluble in water, and not even readily in alcohol; it is a solid crystalline substance, fusing at from 242° to 244°. The authors describe several of the salts of this acid, and also metabromo-thihydrobenzoic acid, $\text{C}_6\text{H}_3\text{BrSH} \cdot \text{COOH}$, fusing at 256°; insoluble in water, and readily soluble in alcohol.

Contribution to Our Knowledge of Zirconium.—Dr. E. Melliss.—The author describes—Bromide of zirconium, a white crystalline powder, readily volatilised by heat, decomposes in contact with water, forming zirconium oxybromide, $\text{ZrBr}_2 + \text{H}_2\text{O} = 2\text{HBr} + \text{ZrBr}_2\text{O}$. The oxybromide of zirconium is $\text{ZrCl}_2 \cdot \text{O} \cdot 4\text{H}_2\text{O}$. Zirconium and iodine do not combine together at all. Zirconium and aluminium-silicium, $\text{Zr}_2\text{Al}_2\text{Si}$, was obtained by fusing together 1 part of zirconium, 5 parts of cryolite, 1 part of aluminium, and 10 parts of a mixture of the chlorides of sodium and potassium.

Final Result of the Action of Chlorine Gas upon Chloronaphthalene.—A. Faust.—The author simply says that the body which has been called β tetrachloro-naphthalene has been found to be enneachloro-dinaphthalene, $\text{C}_{20}\text{H}_7\text{Cl}_9$.

Ortho-Nitrotoluol.—F. Beilstein and A. Kuhlberg.—The authors describe—The sulpho-acid of ortho-nitrotoluol and several of its salts; next, ortho-amido-toluolsulpho acid—

γ dinitrotoluol; γ trinitrotoluol; dinitrotoluol sulpho-acid. The paper winds up with a synoptical tabulated review of para-, ortho-, and meta-nitrotoluol and its derivatives.

Action of Bromine upon Pyro-Tartaric Acid.—B. Lagermark.—This paper is divided into the following sections:—Monobromotartaric acid-anhydride, $\text{C}_4\text{H}_3\text{BrO}_5$, and salts of this acid; tribromopyrotartaric acid, $\text{C}_4\text{H}_2\text{Br}_3\text{O}_5$, and salts of this acid.

Incandescence Phenomenon of Ammonio-Phosphate of Magnesia and Pyro-Phosphate of Magnesia.—O. Popp.—After discussing, at some length, the value of the assertions made in respect of the cause of this well-known phenomenon, the author states that a series of experiments made by him with perfectly pure materials (because, if the ammonio-phosphate of magnesia is not pure—if even a trace of lime or other salts are present, the phenomenon is either not seen at all, or greatly decreased), has proved to him that the cause is due to a change, or conversion, from the crystalline to the amorphous state; a kind of fusion takes place. The corresponding arsenic combination does not exhibit the incandescence, because it is decomposed, on being heated, in a more complex manner, the result of which is the setting-free of some magnesia. The oxides of iron and chromium, when heated as hydrates, also exhibit incandescence; and the author states that the great difficulty experienced in re-dissolving these oxides after ignition in strong acids, is due to the partial fusion they undergo at the moment the incandescence takes place.

Bayerisches Industrie und Gewerbe Blatt, April, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences.

Woody Fibre as a Substitute for Paper-Making Materials, and on Volter's Wood-Shaving and Pulping Machine.—Dr. Landes.

The Manufacture of Paper in General, and on the Quality of the Paper made Now-a-days as compared with that made at More Remote Periods.—J. Bullinger.—These two memoirs are, we regret, too lengthy for any useful abstraction, but contain very valuable hints to paper makers.

Preparation of Spirits from Lichens.—Dr. Stahlschmidt.—The large quantities of lichens (marine as well as terrestrial) found in many parts of Europe may be, indeed, usefully applied in this manner, and thus a saving effected in the consumption of grain for the purposes of distilleries. The author describes the process at length; the cellulose of the lichens or moss is converted into glucose by boiling with from 7 to 10 per cent of the weight of the mass of hydrochloric acid (sp. gr. 1.165) by the aid of steam; the acid is saturated with chalk, and the saccharine matter brought to fermentation; 20 lbs. of moss or lichen yield five litres of spirit at 50 per cent anhydrous alcohol.

The Journal of the Franklin Institute, April, 1870.

This number contains the following original papers and memoirs relating to physico-chemical and applied sciences:—

Carbonic Acid Apparatus.—W. H. W.—The description, illustrated with a woodcut, of an improved apparatus for the estimation of carbonic acid upon the plan of Mohr's well-known contrivance. The use of anhydrous sulphate of copper, jointly with fused chloride of calcium, is recommended as a drier in case hydrochloric acid is used in the analysis.

Corrosion of Iron Water-Pipes.—M. Graff.—The pipes alluded to, made of wrought-iron (boiler-plate), 7 feet in diameter, were completely preserved against corrosion by being painted, while hot, with boiled coal-tar; an attempt to protect the pipes by strips of zinc entirely failed. Nothing is said as regards the cause of the corrosion, but the pipes are used to convey water for drinking and domestic purposes.

Physical Constitution of the Sun.—B. A. Gould.—A lengthy paper discussing various points of scientific interest in relation to this subject.

Diffraction Produced by the Edges of the Moon.—E. C. Pickering.

Coal and Smoke Consumption.—J. T. Rich.—The author describes a contrivance whereby the bituminous coal, used as fuel for locomotive engines on the Pennsylvania railroad, is gradually converted, while serving as fuel, into coke, the combustible gases and volatile matter giving off flame, and the result being a very complete combustion free from smoke; but the question whether steam can be made fast enough is not yet decided.

Journal für Praktische Chemie (double number), Nos. 8 and 9, 1870.

The greater part of this number is filled with Professor von Liebig's paper—

Fermentation and the Source of Muscular Power.

The following original memoirs and papers are also met with in the above-named journal:—

Fluorbenzoic Acid and Fluorbenzol.—Dr. R. Schmitt and Dr. H. von Gehren.—The authors describe at great length the preparation of fluorbenzoic acid from diazo-amido benzoic acid, by treating that substance at a high temperature in a platinum basin with hydrofluoric acid; the reaction takes place according to the following formula:—

the fluorbenzoic acid thus obtained resembles, as far as its physical properties are concerned, benzoic acid; it is, however, far more volatile, fuses at 182°, difficultly soluble in cold, readily in hot, water, as also in ether and alcohol; its aqueous solution exhibits a strongly acid reaction to test paper and decomposes inorganic carbonates very readily; the acid does not act upon glass, is a very fixed substance, which may be even dissolved in concentrated sulphuric acid without decomposition; formula— $C_7H_5FIO_2$, contains 13.6 per cent of fluorine. The authors describe a series of the salts of this acid; the formula of the silver salt is—

calcium salt—

fluorbenzol, C_7H_5FI , is a crystalline solid, boiling at about 183°, fusing at 40°, insoluble in water, and specifically heavier than that liquid, readily soluble in ether and alcohol.

Action of Fluid Phosgen on Some Organic Compounds.—Dr. Th. Kempf.—This lengthy memoir is divided into the following sections:—Action of fluid phosgen upon phenol; action of fluid phosgen upon cresol; action of fluid phosgen upon thymol; action of fluid phosgen upon benzoyl hydride; action of fluid phosgen upon acetone.

Formation of Ozone during Active Combustion.—C. Thau.—The author describes, at length, a series of experiments which prove that during the rapid combustion of substances containing hydrogen, especially gases, a certain though small quantity of ozone is formed; the conditions under which the substance is best obtained during combustion are also fully explained.

Behaviour of Permanganate of Potassa with Sulphuric Acid.—Dr. Spiess.—The author states that while he was engaged preparing from a mixture of permanganate of potassa (the dry salt) and concentrated sulphuric acid ozone, he was astonished by the appearance of violet-coloured vapours, which at first he believed to be due to iodine, and consequently an impurity of the salt alluded to; on investigation, however, no iodine was found at all; on repeating the experiment, the author obtained what he thinks is a new, hitherto unknown, compound, but his researches on this point are not quite finished.*

On Raddonite, a New Mineral, and on Asbolan.—F. von Kobell.—The mineral called raddonite by the author has a specific gravity of 2.8, is black coloured, while in solid lumps its powder is deep brown; it fuses readily before the blow-pipe, yields, with borax, a blue-coloured bead, is completely dissolved by hydrochloric acid, chlorine being evolved; in 100 parts it consists of peroxide of iron, 45.00; oxide of manganese, 13.01; alumina, 1.4; oxide of copper, 14.0; protoxide of manganese, 7.61; protoxide of cobalt, 5.10; water, 13.5; formula—

the asbolan alluded to by the author is a mineral found near Saalfeld; it contains a small quantity of lithia, but chiefly oxide of manganese, which constitutes 54 per cent of the whole.

The Theory of Flame.—K. Knapp.

The Polybromides of the Tetra-Ammonium Bases.—P. C. Marquart.—The first instalment of a lengthy memoir on this subject.

* The editor of this periodical, in a foot note, states that the material alluded to by the author of this paper is permanganic acid contaminated with some sulphuric acid, and also calls attention to the researches on the action of the two substances alluded to, made by Dr. Unverdorben, Dr. Wöhler, and others.

Les Mondes, June 16, 1870.

This number contains, under the title to be presently mentioned, a statement which, although strictly of architectural importance only, we mention because it concerns one of the largest, as well as one of the most celebrated, buildings of the world—

Inclination of the Axis of the Basilica of St. Peter at Rome.—In a letter to the eminent editor of the above-named periodical, it is stated that M. Crozes, a barrister from Albi (France), while temporarily sojourning at Rome, and minutely inspecting the celebrated Basilica (church), found that the main lines (centres) of the dome and the western main entrance of the building, do not, as it should be, coincide, but are no less than 1.5 metres mutually out of the plumb-line. (The building was not constructed by one architect—the dome being the work of Michel-Angelo, and the rest that of Carlo-Maderno.) This defect, it appears, has never even been found out, even in modern days; and, on being consulted on the subject, was found to be unknown as well to the Rev. Father Secchi, S.J., as to Chevalier Martinucci, Professor Sarti, Count Vespingiani, and other scientific and architectural authorities at Rome, who, however unwilling to believe, cannot deny the fact as ascertained, and as stated above, to have been accidentally discovered by a non-professional, but an unprejudiced observer. The matter, as may be readily imagined, is now to be thoroughly investigated; but the writer of the letter above alluded to states that the main fact, as discovered, remains, as yet, undisputed.

June 23, 1870.

Osmose.—Under this heading, the excellent editor of this periodical states that he has received intelligence from the large beet-root sugar manufactory at Arlowetz, Southern Russia, stating that the osmose process has been applied there under peculiarly-favourable conditions, whereby, on the large scale, 35 per cent of sugar has been obtained from the third crystallisation, instead of only 8 per cent as when the usual methods are applied.

The Arènes of Paris.—M. de la Folie.—This author addresses, to the editor of *Les Mondes*, a very lengthy letter, from the contents of which it appears that this building is not at all of Roman construction, but is the work of the King Chilperic (Merovingian race), whose contemporary, St. Gregory of Tours, states, in papers of undoubted authenticity, that this king built arènes at Soisson and Paris. The author, moreover, observes that this statement is fully confirmed by the mode of architecture and materials used, as quite distinct from anything of the kind done by the Romans. The age of the building is, therefore, only thirteen, instead of nineteen or twenty centuries.

NOTES AND QUERIES.

Ozone.—Can any of your readers give me the most expeditious and economic way to produce ozone in quantity?

Atomic Weights.—If $Co_3O_4 + 6(KNO_3) = C_2O_4 = 18.35$, $K_2O = 31.24$, and $Na_2O = 50.41$ per cent, what are the atomic weights of Co, K, Na, and O? An answer will greatly oblige.—A STUDENT AND CONSTANT READER.

Estimating Sulphide and Sulphite of Calcium.—Can any of your correspondents kindly inform me of a method of estimating the sulphite and sulphide of lime in black-ash waste after being oxidised by Mond's process?—ALKALI.

Lead Roofing.—(Reply to "Slates").—The matter you complain of is not of rare occurrence, and its prevention is not an easy matter, since lead which has been painted over is gradually acted upon in the manner alluded to. As a remedy, you may try good asphalt-varnish, used as a paint, or thickly-boiled coal-tar, applied on the metal while hot. But the best of all will be to convert the lead superficially into sulphide (black-coloured) of lead, by washing the lead over with a hot and concentrated solution of a soluble alkaline sulphide; for which purpose the substance known under the name of "hepar sulphuris," of the older pharmacopœias, will answer very well. Galena, crystallised sulphide of lead, is not perceptibly acted upon by atmospheric agency; and the amorphous sulphide of lead is insoluble in water, even when containing carbonic acid.

TO CORRESPONDENTS.

* Vol. XXI. OF THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 11s. 6d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxii. commenced on July 1st, and will be complete in twenty-six numbers.

J. Muspratt and Sons.—Received with thanks.

S. Beswick (Paterson, New Jersey).—Many thanks for your communications; they shall be inserted in an early number.

One of your Subscribers.—A description of "The Ozoniseur," is not given in M. Houzeau's memoir.

F. W. Clarke (San Francisco).—Any light tar oil will serve as fuel for Griffin's oil blast lamp; the price would be £2 10s. Our publisher would undertake the forwarding of any apparatus you may require.

THE CHEMICAL NEWS.

VOL. XXII. No. 555.

PRELIMINARY NOTE ON A NEWLY-DISCOVERED PROPERTY BELONGING TO RUBIDIUM AND CÆSIUM,

AND ON THEIR OCCURRENCE IN SEA-WATER AND IN
MARINE PRODUCTS.

By E. SONSTADT.

WHEN chloride of calcium and oxalate of ammonium are added in sufficient quantity to a neutral or alkaline solution containing rubidium and cæsium, the whole of these alkalies falls with the precipitated oxalate of calcium, from which they cannot be washed out. Other alkalies, if present, remain in the solution. Rubidium and cæsium are thrown down in like manner along with carbonate of calcium, but the precipitate is slightly decomposed by prolonged washing with pure water; nevertheless, the filtrate, with a moderate quantity of washings, is spectroscopically free from these alkalies. With sulphate of calcium, the behaviour is similar, but the compound formed is more soluble than from the calcium-salt; and from a large quantity of sulphate of calcium, containing but little of these alkalies, most of the latter may be separated by much washing. Rubidium and cæsium fall, also, with tungstate of calcium, but the compound is almost entirely decomposed by much washing. When a solution of chloride of calcium containing rubidium and cæsium is partially precipitated by oxalate of ammonium or carbonate of sodium, a portion of the rare alkalies remains in solution with the remainder of the calcium-salt. A strong solution of chloride of calcium, whether in water or in alcohol, dissolves the chloro-platinates of rubidium and cæsium rather freely, and the latter are not precipitated on dilution. Neither carbonate of magnesium nor alumina carry down with them rubidium and cæsium salts.

Sea-Water.—If oxalate of ammonium is added in excess to sea-water, and the well-washed precipitate ignited, moistened with nitric acid, and examined in the spectro-scope, the Rb and Cs lines will be distinctly seen in a good flame of dry hydrogen. Whether they would also be visible if examined in the usual gas-flame of a Bunsen's burner, I have no opportunity of trying. One ounce of sea-water gives material enough for several trials in the spectro-scope. When, however, sea-water is evaporated to dryness, and the residue treated with a small quantity of water, filtered, the filtrate evaporated to a very small bulk, and, after addition of nitric acid, examined in the spectro-scope, only the sodium and potassium lines are visible, nor can the rare alkalies be detected in the filtrate by the help of precipitation by platinic chloride.

Seaweed.—I became aware of the presence of other than the common alkalies in seaweed more than eighteen months ago. Rubidium and cæsium may be detected by the careful application of ordinary methods, not only in mother liquors, but in "kelp salts," in sulphates and chlorides of potassium, and in the drainage of wet seaweed.

Shells.—A few shells from the sea-shore have been examined by igniting chips, moistening with nitric acid, and introducing to the hydrogen-flame before the spectro-scope. All gave the Rb and Cs lines apparently with equal intensity and with one another, and with lime obtained direct from sea-water. Among the shells examined, were those of the oyster and acorn-barnacle.

Limestone.—Lime from Castletown, in the Isle of Man, showed in spectro-scope exactly like the shells above-named. About a pound-weight of this lime was put into a funnel, and slowly washed for about ten days; it still

showed the Rb and Cs lines, but the latter very faintly. The filtrate was evaporated to a small bulk, air being blown through until a scum no longer formed. The liquid portion was then rich in potassium salts but did not contain a spectroscopic trace of Rb or of Cs. Every trace of these alkalies that had been washed out of the lime remained with the carbonate of calcium formed during the boiling down. The lime brought to Ramsey, from Castletown, contains many lumps which scarcely "slake" on wetting; such lumps are locally called over-burnt, but a qualitative examination showed that they differed from good lime only in containing a larger proportion of clay. As the clay in ordinary limestone is usually supposed to be the source of the alkalies, it might have been expected that this clayey lime would have been richer in rubidium and in cæsium than the other sort. But the contrary was the case. *Marl*, from near Ramsey, which contained much carbonate of calcium, with clay, shows no line of Rb and Cs when examined in the spectro-scope in the same manner as the other substances mentioned. The average of such Castletown lime as I have examined contains about 5 per cent of clay, equal to about half that proportion in the limestone before burning.

I have made some approximate quantitative determinations of the proportion of rubidium and of cæsium contained in some of the substances mentioned in this note; but, as these results are, as yet, only roughly approximate and incomplete, I reserve them, as well as all theoretical considerations, for another time. But, this much is already clear—these alkalies can no longer be styled rare, since even in a few grammes of sea-water they can be easily recognised.

GENERAL DOCTRINE OF SOLUTIONS.

SWEDENBORG IN 1721-2 AND DALTON IN 1840.

By S. BESWICK.

THE practical scientist will contend that we must reserve the honours of science and discovery for those who reduce conjecture to truth by the evidence of experiment. This rule is well recognised and established, and we accept it as founded in justice and necessity. The first experimental demonstrator of the general doctrine of solutions, and he only, shall have the honours. Practical Science has no religious prejudices, and acknowledges no favourites. If Swedenborg lays down clearly the general doctrine of solutions, and gives definite experimental illustrations of the doctrine, then, we claim, he has fulfilled the conditions, and reduced conjecture to truth by the evidence of experiment and observation; and we expect that critics of the experimental school will give him the honours promised to be reserved for only such as he has proved to be.

The general doctrine of solutions approximates in importance to that of the atomic theory. Dalton appears to have been the first to make this important discovery amongst the chemists of this century. He first observed it about the year 1840, at which time he pronounces it a new discovery. But Swedenborg had published the same doctrine, with abundant illustrations, so far back as 1721-2. His statements are clear, full, and well founded. The following paragraphs are a few which we have taken from his "Principles of Chemistry":—

"When the particles of water contained in the salt are added to the particles of the fresh water, the number of the latter is increased by the number of those in the salt, *that is, they increase the bulk by their own bulk; but it is not so with the saline particles, which, only, occupy the space in the interstices, according to the demonstrations in the preceding theories.*

"The saline particle in water does not increase the space, but only occupies the void; so that, whatever quantity of salt there may be in the water, the volume is

not in the least increased by the mere particle of salt; but the weight is augmented. Whatever increase of bulk there may be is derived from the particles of water contained in the mass of salt, as will be mentioned hereafter. Hence the saline particle, according to our theoretical delineation, possesses the following qualities:—It can flow easily in water; it fits the convexity of the watery particles; it constitutes one volume with them; it may be separated from them by the slightest touch or motion; it is constantly attended by six aqueous globules, whether it move upwards or downwards; and, by this connection, there is no increase whatever in the volume of the water, but only in the weight.—(P. 31).

"We have now to take into consideration the increase of the solution in bulk and weight. For it is well known that salt water is heavier than fresh; so that the degree of saltiness may be determined by the weight. And this fact, likewise, indicates that the saline particles do not require any separate place for themselves, but that they are contained in the interstices between the particles of water. We have shown that the mere particles of salt cannot at all add to the bulk, but only to the weight, because they occupy the spaces between the aqueous particles."

These theoretical statements are clear and explicit; indeed, it would be difficult to express an idea in more definite and positive terms than those which Swedenborg has used in the above passages. I am not aware that any conjectures of this important fact were ever published until it was actually discovered by Dr. Dalton, in the year 1840, about 119 years after Swedenborg had published it in his "Principles of Chemistry." In the year 1840, Dalton discovered that dry salts have no volume in solution up to the point of saturation. He read an essay to the Manchester Literary Society, October 6th, 1840, on the "Quantity of Acids, Bases, and Water in Salts," from which we cite the following passages:—

"I was greatly surprised at the results. If the salt was anhydrous, it would all go into the bottle, exactly filling it to the grain, showing that the salt enters into the pores of the water.

"The water and solid matter are the same in bulk as the water itself. The solid matter would go into the pores of the water.

"The solid matter only adds to the weight.

"I have tried the carbonates, sulphates, nitrates, muriates or chlorides, phosphates, arseniates, oxalates, citrates, tartrates, acetates, &c.; and have been universally successful. Only the water adds to the bulk, and the solid matter adds to the weight.

"Suppose I take water of 1000 grains' weight, and the sulphate of magnesia and water of 1112 grains' weight: they will be of the same bulk."

And, in a paper read at a subsequent date, to the same society (*Manchester Memoirs*, vol. i., new series), he expressly declares that this fact was new to him, and to the scientific world at that date (1840); the discovery of which almost rivalled that of the atomic theory. He says:—

"This fact was new to me, and, I suppose, to others. It is the greatest discovery that I know of, next to the atomic theory."

In nearly all these passages, the words are italicised by Dalton himself. The principal, if not the only, reason for writing the first essay was to publish to the world what he regarded as a new and important discovery—that acids, bases, and salts do not add to the bulk, but only to the weight, of solutions. The question of priority of publication can be readily seen from the following comparison of dates and statements.

Swedenborg in 1721-2.

"We have shown that the mere particles of salt cannot at all add to the bulk, but only to the weight, because they occupy the spaces between the aqueous particles."—(P. 51).

Dalton in 1840.

"The water and solid matter are the same in bulk as the water itself. The solid matter only adds to the weight. The solid matter would go into the pores of the water."

The same fact is as broadly announced by Swedenborg as by Dalton, and in terms whose identity with those used by Dalton cannot be disputed. Indeed, the fact is more tersely and clearly expressed by Swedenborg than by Dalton.

Drs. Patenfair and Joule have pursued similar researches, supplemental, in point of time, to those of Dalton; and have come to conclusions coinciding with results first obtained by the author of the atomic theory. Acids, bases, salts, add nothing to the volume or bulk of solutions, but only to their weight. Other chemists have obtained like results. It was thought that Dalton's experiments and alleged discovery required the verification of additional testimony and experiments before such a remarkable law was acknowledged; and these latter researches were designed to give this verification.

We claim that the Swedish philosopher, Swedenborg, was the first to suggest, verify, publish, and place on record, in a work called "Principles of Chemistry," the date of whose publication is certain, the general doctrine of solutions. The right to a scientific idea or theoretical discovery is secured by the act of publication; and, in virtue of such act, priority of conception and verification of the general doctrine belongs indisputably to Swedenborg.

ON THE

POTASSIO-COBALTIC NITRITE KNOWN AS FISCHER'S SALT, AND SOME ANALOGOUS AND RELATED COMPOUNDS.

By SAMUEL P. SADTLER.

(Concluded from p. 17.)

HAVING now made a complete statement of all my analytical results in the case of Fischer's salt proper, as well as in this series of analogous and related compounds, which I have described in this connection, and noticed the conclusions to be drawn from them, before summing up my argument I will examine how the results of Stromeyer, Erdmann, and Braun compare with my own. In the first case, I think the last argument drawn from the similarity of weights of double nitrite and double sulphate in the protoxide-salts, and the difference of weights of double nitrite and double sulphate in the sesquioxide-salts, effectually precludes our assigning a formula like that of Stromeyer (in which $2(\text{N}_2\text{O}_3)$ combines with Co_2O_3) to the normal Fischer's salt. The salt Stromeyer analysed was probably a mixture of "acid" and "neutral" salts, as he speaks of adding "a little acetic acid." It is easily seen that a mixture of the "acid salt" and the yellow "neutral salt" would give figures approximating to his. Erdmann's results correspond, in the main, to the analysis of my second preparation. The only difference, then, is that I have introduced a generalisation, which, I think, my figures fully justify. With Braun's results I am hardly able to make a comparison, as he made his preparation in a manner totally different from that followed by either Erdmann or myself. His formulae, as might be inferred from my statement of them in the beginning of this paper, I am still less able to accept.

To sum up briefly, the reasons for regarding Fischer's salt as a potassio-cobaltic nitrite, having the essential formula $\text{Co}_2\text{O}_3\text{NO}_2 + 6(\text{KNO}) + \text{aq.}$, are:—

x. The liberation of O at the moment of its formation,

and the rapidity with which, under these circumstances, the salt forms, would seem to justify the assumption.

2. The analyses of six distinct preparations sustain it.
3. The existence of corresponding sodic and ammoniac salts is proved by analysis.
4. The formation of substitution-compounds exactly analogous to well-known salts is proved by analysis.
5. The analogy of Fischer's salt to double cyanides, chlorides, and nitrites proved to contain a similar hexatomic atom.

6. The difference of ratio between the weights in the protoxide and sesquioxide salts is marked and constant throughout.

Accepting these proofs, we will sum up with equal brevity the formulæ of the salts analysed on this view—

Tri-potassio-cobaltic nitrite,	$\text{Co}_3\text{NO}_3 + 6(\text{KNO}_3) + \text{aq.}$
Di-sodio-cobaltic nitrite,	$\text{Co}_3\text{NO}_3 + 4(\text{NaNO}_3) + \text{H}_2\text{O.}$
Tri-sodio-cobaltic nitrite,	$\text{Co}_3\text{NO}_3 + 6(\text{NaNO}_3) + \text{H}_2\text{O.}$
Di-ammonio-cobaltic nitrite,	$\text{Co}_3\text{NO}_3 + 4(\text{NH}_4\text{NO}_3) + 2\text{H}_2\text{O.}$
Tri-ammonio-cobaltic nitrite,	$\text{Co}_3\text{NO}_3 + 6(\text{NH}_4\text{NO}_3) + 2\text{H}_2\text{O.}$
Lutecobaltio-cobaltic nitrite,	$\text{Co}_3\text{NO}_3 + \text{Co}_3\text{I}_2\text{NH}_3\text{.6NO}_3 + \text{H}_2\text{O.}$
Roseocobaltio-cobaltic nitrite,	$\text{Co}_3\text{NO}_3 + \text{Co}_3\text{I}_2\text{NH}_3\text{.6NO}_3 + \text{H}_2\text{O.}$
Xanthocobaltio-cobaltic nitrite,	$\text{Co}_3\text{NO}_3 + \text{Co}_3\text{I}_2\text{NH}_3\text{.6NO}_3 + \text{H}_2\text{O.}$
Potassio-dicobaltous nitrite,	$2(\text{Co}_2\text{NO}_3) + 2(\text{KNO}_3) + \text{H}_2\text{O.}$
Potassio-monocobaltous nitrite,	$\text{Co}_2\text{NO}_3 + 2(\text{KNO}_3) + \text{H}_2\text{O.}$

These, it will be seen, are capable of ready conversion into atomic formulæ, thus:— $\text{Co}_2\text{VI}[\text{K}(\text{NO}_2)_2]_6$ and $\text{Co}_2\text{VI}[(\text{Na}(\text{NO}_2)_2)_2(\text{NO}_2)_4]_4$, and so on.

In the course of my examination of these salts, I had an opportunity of comparing the relative merits of the different analytical methods employed. A brief statement in regard to them may be of some value.

1. Determination of Co and K. The double sulphate method, already alluded to, was first proposed by Gibbs and Genth;* and I find it to give extremely close results. Sulphuric acid is added to the weighed portion of the salt, in a porcelain crucible, which is then heated carefully, either by a ring gas-burner from above or by radiation while supported in a sheet-iron crucible. After the nitrous acid is all driven off, with most of the excess of sulphuric acid, the sulphates begin to fuse, and as the last trace of sulphuric acid goes off they pass into calm fusion; they will then bear a very considerable increase of heat without farther decomposition. I found this method capable of extension to both the soda-salts, as well as to the protoxide-salts, the double sulphates formed having, of course, a constitution depending upon the proportion of the bases in the original salts. The soda-sulphates did not appear, however, to possess as perfect a fusibility as the double potash-sulphate from Fischer's salt; while the double sulphates from the protoxide potash-salts were also less fusible, in proportion to their greater ratio of Co. I give an instance in proof of the accuracy of this method. Four determinations of $\text{CoO} + \text{K}_2\text{O}$ were made in Preparation No. 6 of Fischer's salt, in the manner described. The percentages of double oxides were—48.71, 48.69, 48.66, 48.71. This method was tried by Gauhe,* without obtaining good results. Several points are to be noticed, however. The salt in which Gauhe sought to verify the composition of the double sulphate was plainly a mixture of "acid" and "neutral" salt. He says, "After some days, small amounts deposited." This was before Erdmann's paper had appeared. Again, Gauhe will find that Gibbs and Genth never even mentioned the use of $(\text{NH}_4)_2\text{CO}_3$ in this connection; so that his experiments were plainly made under different conditions from those proposed.

2. Determination of Co. I prefer to determine Co as neutral CoSO_4 . We have the advantage here of determining the Co in the form of a compound of definite atomic weight, thus lessening our errors of analysis. The cobalt is precipitated from the solution of the double sulphates as CoS , washed with hot sulphide of ammonium water, dried and roasted, and then converted into sulphate with the aid of aqua regia and sulphuric acid. The

results are good, although not so exact as in the case of the fusible double sulphates. I also determined Co as metal, by H, after its precipitation as hydrated oxide by Cl and acetate of soda—a method proposed by Popp.* Instead of Cl, I found it far more convenient in practice to use a strong solution of Cl_2O_2 , which is a powerful oxidising agent, and, as it can be kept, becomes a useful laboratory reagent. This method, however, does not always give good results, on account of the difficulty of washing the hydrated Co_2O_3 till free from alkali.

3. Determination of the N. This was done first by the modification of Bunsen's† method proposed by Dr. W. Gibbs,‡ which space will not permit me to give in detail; the reader is therefore referred to the original paper. Suffice it to say that, for nitrates and nitrites to which it is applicable, it is an excellent method. The loss of the combustion-tube can be nothing but N and H_2O . If, therefore, the CaCl_2 tube retains the H_2O accurately, the remainder is N. Whether, therefore, the H_2O is accurate or high from hygroscopic moisture, the nitrogen must be accurate, being subject to no source of error.

The nitrogen was also determined by volume, using the Sprengel pump. This method was first proposed by Frankland|| for nitrogen in analyses of potable waters, but he did not apply it then to organic analysis. The application, however, had been made in this laboratory, by Dr. Gibbs, some months before Dr. Frankland's paper was received. A vacuum is first made in the combustion-tube, by means of the mercury-pump; the delivery-tube from the pump is then connected with a Simpson's receiver, and the vacuum destroyed by heating some CO_2 placed in the anterior portion of the tube. Any excess of CO_2 is absorbed by the KHO solution in the receiver. The combustion is now made. A final vacuum is then obtained by the pump, and the receiver disconnected. After a short time, the gas is transferred to a eudiometer-tube, and measured according to the methods of gas analysis. The results are generally good, but depend upon the vacuum obtained at the beginning and end, on the perfect combustion, and on the perfect transfer of the gas.

In conclusion, I would present my grateful acknowledgments to Dr. W. Gibbs, to whose kindness I am indebted for the selection of my subject, for the use of materials, and for many valuable suggestions during the prosecution of my work.—*Am. Jour. Sci.*, lxi., 189.

AIR-POLLUTION BY CHEMICAL WORKS.

A MANUFACTURER, having realised his primary object of making what he can out of the materials which pass under his hands, and having utilised all that he deems valuable in them, finds there is yet another need to be fulfilled;—he must get rid of his refuse, and that as speedily as possible. Our present object is to watch this latter operation, and, losing sight of the beautiful or useful results of his work, to direct our attention to what is waste or refuse, and enquire how he disposes of it. When this is solid and bulky, it must be removed at the cost of much labour, and a place must be provided where it can be deposited. When the refuse is a liquid, the process of getting rid of it is generally less expensive; it will flow away in the water-courses, if only proper drains and passages are provided. When the refuse is gaseous, this process of removal is easier still: no passages need be cut, no culverts nor bridges built; the vapour can be allowed to pass into the air, and is blown away.

In each of these cases the manufacturer's object is attained; he is rid of the refuse, and has room for renewed work. Unfortunately, however, although he is rid

of it, his neighbours are not so; they find, on the one hand, that the water of their brook is no longer fit for use nor pleasant to look at, and the air they breathe is polluted with unsavoury and noxious vapours. Where a manufactory of this kind stands alone, or where only those who are dependent on it for their subsistence dwell in its vicinity, this state of things goes on for a long time without calling forth much complaint. Sooner or later, however, complaints must come; we cannot all live at arm's length. Population increases, we are pressed together; and, valuable though the various products of manufacturing industry may be, pure air and pure water are more valuable still. Yet we cannot do without the manufactory, unless we return to barbarism. A naked savage, eating uncooked roots, erects no chimney to pour its black or acrid vapour into the air; he discharges the liquor from no dye beck into the clear brook of the glen—but he remains a savage. We must keep our manufactories: by their products we are warmly clothed, our houses are firmly built and are decorated with colours; the wind is shut out by panes of transparent glass; the paper on which we write is white and fair. These and a thousand other things are the results of many a mechanical or intricate chemical process, the waste products from which—solid, liquid, and gaseous—are unpleasant enough.

If, then, we will not go back to barbarism to get rid of our smoke and our dirty water, can we go forward, and, by greater skill, diminish or suppress them? The answer must be, "Yes." Yet those only who have to work out the problem know with what difficulty this answer has, in many cases, been given; whilst in many it is not given yet.

The materials which the manufacturer throws away we have already classed, in correct school-room fashion, as solid, liquid, and gaseous. With the first of these the manufacturer alone is concerned, and it may be safely left in his charge. The more of it he produces, the more must he expend in its removal, the more land must he purchase on which to deposit it; and, if he throws away that which is valuable, he is the chief loser. We may therefore safely leave him, with certain reservations, to look after his solid refuse, knowing that no sharper impulse can be applied to induce him to diminish its amount, or to save what is valuable in it, than the spur of self-interest which already exists. We say it may be safely left in his charge; but, if, through some process of fermentation or change, a portion of it shall slip out of his custody, and yield, after rain, a noxious liquid to drain into the nearest brook, or a gaseous escape to contaminate the air around, it falls back into the two other classes.

For the present, we propose to direct attention to the latter of these two classes only—the gaseous. In doing so, we would first dwell on the magnitude of the evil which may and does arise from the pollution of the atmosphere by gases discharged during the carrying on of various manufacturing processes; secondly, on the state of our laws on the subject; and, thirdly, as to the direction which further legislation on the subject should take.

The evils complained of are not uniformly spread throughout the country, and do not come under the observation of anyone. Some districts are found to be specially suitable for carrying on a particular manufacture; so, throughout the country, we find works of a certain kind grouped together. Those who reside in the districts known as "manufacturing" are too familiar with the evils arising from noxious vapours floating in the air to need any setting forth of their extent, unless, indeed, familiarity with these evils has dimmed the perception of their magnitude. In Staffordshire, the so-called "black" country is a district of many miles in extent, blasted by the smoke of the iron-furnaces; in it not a tree can be found, and scarce a blade of grass. Near St. Helens and Widnes, in Lancashire, scarce a living tree is seen in the direction towards which the prevailing winds blow. And, in the valley of Swansea, thickly set with copper-works, not only are the hill-sides bared of the green forests which

once waved there, but the underwood, the shrubs, the hedge-rows, the grass itself, is gone; and, to complete the desolation, when the roots and fibres which permeated the soil died and rotted, the soil itself, no longer able to withstand the action of the rain, was also washed away, leaving only bare heaps of stone and gravel. These (more like huge railway-embankments than natural hill-sides) suffer yet another injury; for the rain, not now absorbed and held back by tree, shrub, grass, roots, or soil, falls on the bare hill-side, as on the slated roof of a house, and as quickly runs off it, ploughing the ground in its headlong course, making each rippling streamlet into a torrent, even during a moderate shower. And still the desolation is not fully described; for, when the even adjustment of nature is disturbed, who shall say where the derangement will stop? Here the grass, the soil, is gone, and with these the insects and birds, with the exception of a few sparrows.

The manufacturing processes which may give rise to noxious vapours are numerous. The French, in the elaboration of their sanitary code, enumerate seventy-four.

These noxious vapours may do injury of two kinds—injury to animal life and to vegetation.

Injury of the former class, though real and widespread, is a matter less easily brought to the measure of money than that of the second class. People are annoyed at a vile smell arising from some manufacturing process, and, by its continuance, are affected in health; but they do not assess the damage in money, and sue for it at law, except in so far as property is injured. Where, however, in an already populous district a factory is established, the emanations from which can be proved to be injurious to human health, there is power for suppressing the nuisance; for, under the Sanitary Act (18 and 19 Vict., c. 121), the "Local authority, when moved by its medical officer of health, or by two legally-qualified practitioners, or by ten householders residing in the district in which the nuisance exists, is bound to complain to the magistrates (two lay, or one stipendiary), and to prosecute the offenders. The penalty, if the case is proved, is a fine of from 40s. to £5 for the first conviction, £10 for the second, and for each subsequent conviction a sum double the amount of the penalty imposed on the last preceding conviction, but so that such cumulative penalty do not in any case exceed £200."

The operation of the law here is clear, and generally satisfactory. This clearness, however, ceases when we turn to the working of the law in cases of injury done to vegetation. The question is not now whether any damage is done to the farmer's crops and trees, but *how much*; for, if an important manufactory is carried on, giving employment to a large number of workmen, producing articles of general value, and returning a handsome income to the proprietor, it would not be wise to put a stop to all this producing power because it of necessity entails a small amount of collateral damage. Rather let those who carry on this lucrative manufacturing business compensate those who are injured by it, and consider that they have only fairly earned that amount which remains when, from their gross profits, they have deducted this charge. In this way we have a gauge by which to determine the amount of forbearance which the public shall exercise towards a manufactory doing obvious damage to the vegetation around it.

If a factory produces a revenue of £1000 to its proprietors, and at the same time injures neighbouring vegetation to the extent of £100, it clearly does more good than harm: the farmer is compensated, and £900 is honestly earned after everyone is satisfied. Put, however, the figures the other way. Suppose the works, while earning £100, to do £1000 worth of damage, and the proprietors compelled to pay this; it will require no injunction from the Court of Chancery to make them close the works, or else to improve the manufacturing process so as materially to lessen the damage done.

But we have hitherto considered only the relations of the manufacturer and the farmer, imagining the smoking chimney to be surrounded by corn or clover, orchards and hedge-rows. All these have a known market value, and can be paid for with money. In place of the farmer with his marketable crops, imagine him or his landlord dwelling in the old house of his fathers: the trees which surround his cottage or his mansion are of ancient growth; the place is his home. What money shall compensate for its loss? He may be rich, and put little value on pecuniary compensation. He will feel himself grievously wronged when, his trees being killed, he is offered money in place of them.

This might be said, however, in all cases where the sanctity of private property is invaded. When a railroad is planned, which is to carry a nation's traffic, it will disturb many an ancient hall and many a cottage home. The money equivalent is paid the owner; but, in his eyes, this is often no sufficient compensation. He must, however, bow to his fate, and give way before the greater good of the many. So in the case where a man sees every year the noble trees vanish from his land,—from the ancient domain that has been held in quiet enjoyment by his family through many generations,—and feels himself driven from it by the advancing tide of manufacturers. He is much to be pitied; for, let him be paid ever so liberally for the damage actually done to the estate, he is not compensated. Yet he must submit, and suffer personal loss for the public benefit.

Fortunately, however, these cases are exceptional; generally those interested in the land can be fully compensated in money for all they lose. A farmer who should get £100 for the produce of his wheat-field is content if it brings him in only £50 in the market, provided he can get the remaining £50 by way of damages from the neighbouring chemical manufactory. A question here at once arises. Will he have much difficulty in obtaining from the manufactory the £50, the proved amount of his loss? If the manufactory is standing by itself, he probably will have no great difficulty. If the demand is resisted, his course at law is plain. He proves that, on a certain day, or on many days, the smoke of the offending chimney was seen to fall upon his land; that soon afterwards the crops were visibly injured, in such a way as is known to be caused by chemical smoke. He also further proves, by the assistance of agricultural valuers, that the amount of the damage done is an equivalent of the sum of money he now claims. This chain of evidence is usually so conclusive that the farmer wins the day.

Suppose, however, that, in place of one chemical work being near the farm, there are several in a group, from all of which the smoke approaches simultaneously. These works may be of different kinds: there may be alkali-works and copper-smelting works, glass works and potteries, with chemical works; whose various processes and products defy enumeration. How shall the farmer discriminate? or, rather, how shall he criminate? How shall he fix on the culprit among such a motley crowd of evil-doers? Let us suppose him calling on the first in order, and making his complaint against him, as the one he thinks most likely to have been the offender. The manufacturer explains to him, in the clearest manner, that, from the nature of the processes he carries on and the care with which all injurious vapours are avoided or condensed, he cannot have injured the land. Perhaps it was his friend of the neighbouring works, whose processes are different from his own. Doubtless this gentleman would be equally clear and conclusive in his explanations, and would pass our farmer on once more, to be sent, in turn, from one to the other, but to get redress from none.

The farmer soon learns that the only way in which he can obtain compensation from any of the chemical manufacturers is to fix on one of the works (perhaps the one nearest his land, or the one with the highest chimney), and to watch till he thinks he can distinguish the smoke from it come upon his farm. On that he fixes; and,

shutting his eyes to the other works, and forgetting the injury they probably do him, charges the proprietor with the whole of the damage he has sustained. The judges and juries before whom such cases come for trial are in great difficulty. They know that the manufacturer in question has not done all the damage alleged; yet they have no power of apportioning it between him and other offenders. Therefore, as some of the damage has been proved to come from the defendant's works, they give a verdict for the plaintiff.—*Quarterly Journal of Science.*

(To be continued.)

ON THE ANILINE OR COAL-TAR COLOURS.*

By W. H. PERKIN, F.R.S.

(Continued from p. 19).

THE first apparatus used in the manufacture of nitrobenzol, for the preparation of aniline for the mauve dye, is shown in Fig. 1. It consisted of a large cast-iron cylinder, *a*, fitted with a stirrer, *b*, and closed with a door, *c*, fastened by a cross-bar and screw, *d*. This cylinder was capable of holding between thirty and forty gallons. It was provided with two necks, *e e*, one for the introduction of the benzol and sulphuric acid, which were supplied through a syphon tube; the other for the exit of nitrous

FIG. 1.

fumes. This last was connected with an earthenware worm, to condense any benzol which might be volatilised by the heat of the reaction. The nitrate of sodium was always introduced into the cylinder before the door was fastened up and luted. Until the preparation of nitrobenzol was understood, there was a great amount of uncertainty in its manufacture, and several explosions occurred, but fortunately without causing any injury to the workmen attending the apparatus. These explosions originated generally from the liberation of too much nitric acid from the nitrate of sodium, by the sulphuric acid, before the formation of nitrobenzol had begun, so that when it started, the chemical action set in with such energy that an explosion ensued. After a few of these unpleasant occurrences, however, sufficient experience was obtained to get the manufacture under control. Apparatus of a much more extensive character has since been substituted for the cylinders. In Figs. 2 and 3 you get a view of the apparatus now used in England for the manufacture of nitrobenzol.

This apparatus consists of large cast-iron pots, *a a a*, about 4 feet 6 inches deep, and 4 feet 6 inches wide; they are arranged in rows, and provided with stirrers, worked from a shafting by means of bevel wheels. This arrangement will be seen from the section, fig. 3; the covers of these vessels are also made of cast-iron, and are in two pieces, *b b'* (Fig. 3), of unequal size, provided with a tall

* The Cantor lectures, delivered before the Society of Arts.

FIG. 2.

FIG. 3.

rim, and so arranged that cold water may be kept circulating over their surface; this assists in condensing the benzol, which would otherwise distil away by the heat of the reaction. Through the larger half of the cover the spindle of the stirrer, *c*, passes, and on account of the difficulty of keeping a stuffing-box in order when using the powerful chemicals necessary in this manufacture, a kind of water-joint has been substituted. It is necessary that it should be deep and rather capacious, as seen at *d*. Instead of filling this joint with water, which would absorb the nitrous fumes, and produce an acid solution, which would soon destroy the apparatus, the joint is filled with nitrobenzol; a cast-iron tube, *e*, passes through the lid to carry nitrous fumes; this is also cooled, so as to condense any benzol vapour which may have escaped the cooling action of the lid; small pipes are introduced through another opening for the purpose of supplying the necessary chemicals. Besides these there is a large opening, *f*, in the smaller half of the lid, for the purpose of introducing any of the products, which may be added in large quantities at a time. At the bottom of these large vessels are openings for running out the finished product.

The process of preparing nitrobenzol with a mixture of sulphuric acid and nitrate of sodium in place of nitric acid, may be carried on very well in this apparatus, provided sufficient sulphuric acid be employed to produce an acid sulphate of sodium, as this will be found quite fluid at the close of the operation, and can be freely run out at the small outlet. A mixture of strong nitric acid and sulphuric acid is now usually employed for the conversion of benzol into nitrobenzol. In working by this latter method the entire charge of benzol is first introduced through the large opening in the lid; this is then closed and the stirrer set moving; the nitric and sulphuric acids are then cautiously run in through the small pipes, care being taken not to add too much nitric acid, until the red fumes begin to appear. After all the charge of acids has been added, and the reaction has perfectly ceased, the product is drawn off. At first a mixture of sulphuric and nitric acids runs out, and then the nitrobenzol; this is collected separately and purified,

first by agitation with water, and then rendered perfectly neutral by means of a dilute solution of soda. Should it contain any unconverted benzol, this may be distilled off by means of steam. On the Continent, manufacturers do not appear to have succeeded well in manufacturing nitrobenzol; when it first became a commercial article, their difficulty appears to have arisen from the fact that they experimented in earthenware vessels, which are both dangerous and unsuitable, and it was not until information was obtained from England, I believe, that they were able to produce this body at a moderate price.

We will now pass on to the processes for converting nitrobenzol into aniline. I have already mentioned that Zinin was the first who discovered that nitrobenzol could be converted into aniline, or, as he termed it, benzidam. His process consisted in treating an alcoholic solution of nitrobenzol with ammonia and sulphuretted hydrogen; but, although the discovery of this process was one of great importance from many points of view, still it was very tedious. Bechamp, however, found that by employing a mixture of acetic acid and finely divided iron instead of ammonia and sulphuretted hydrogen, the nitrobenzol was very rapidly converted into aniline, and this process has been found the best yet proposed for manufacturing aniline in large quantities. Many other reagents have been suggested, as arsenite of sodium, powdered zinc, &c., but none of them have been found so advantageous as iron and acetic acid.

In carrying out Bechamp's process, cylinders like those used for nitrobenzol (Fig. 1) were originally employed. The cylinder was set in brickwork, and heated by means of a small furnace, iron borings were first introduced, and

the door fixed in its place air-tight. One neck was connected to the upper extremity of a cast-iron worm by means of a pipe called an adapter; the second neck being fitted with a syphon-tube, for the introduction of the nitrobenzol and acetic acid. In working on the large scale it is necessary to add the nitrobenzol and acetic acid in small quantities at a time, otherwise the reaction is so violent as to almost burst the apparatus: by working carefully, however, there is no need to fear any difficulties, especially if the stirrer is well used. By the time all the charge has been introduced, a quantity of fluid will have distilled over; this is returned into the cylinder and the fire lit, and the aniline distilled off.

The principal change which has taken place in this process consists in using high pressure or superheated steam for the distillation instead of fire, and working the apparatus by means of a steam-engine instead of by hand. In Fig. 4 is shown a sketch of the apparatus now generally employed for the preparation of aniline.

You will observe that the stirrer, which is worked by bevel wheels, has a hollow shaft or spindle, *a*, as seen in the section. This is ground to an elbow, *b*, connected to the steam main, *c*, and held down by a screw, so that when the steam is turned on, it passes through the hollow elbow down the shaft, and then blows out at the bottom, *d*, among the products; and in this manner the aniline is volatilised, and passes with the steam through the neck, *e*, and is condensed by a worm, not shown in this drawing. Aniline thus obtained is generally redistilled, and sometimes with a little lime or caustic soda, for the purpose of decomposing a body called acetanilide, which is often produced in the manufacture of aniline,

FIG. 4.

especially if the operation is conducted over a fire instead of with steam.

Commercial aniline generally appears of a pale sherry colour; when chemically pure, it is colourless, but if kept long it becomes quite brown. It possesses a peculiar odour, which is slightly vinous when the aniline is pure. It burns with a smoky flame, but is not very inflammable; its boiling-point is 182°C . One of its most characteristic reactions is its power of producing a blue or blue-violet colouration with chloride of lime, to which I shall again have occasion to refer. Aniline differs entirely from benzol and nitrobenzol, being perfectly soluble in dilute acids. This is owing to its being an organic base, and forming compounds with acids. Thus, with hydrochloric acid, it forms hydrochlorate of aniline; with sulphuric acid, sulphate of aniline, &c.

We will now, in a very rapid and general way, glance at the chemical changes which take place in connecting benzol with nitrobenzol and aniline.

Benzol, as I have already stated, is a hydrocarbon, *i.e.*, a body composed of hydrogen and carbon only; it is represented by C_6H_6 . This is treated with nitric acid, which contains HNO_3 .

The nitric acts upon the benzol and introduces its nitrogen and part of its oxygen, at the same time removing hydrogen and forming water.

Nitric acid. Benzol. Nitrobenzol. Water.

Nitrobenzol, when treated with iron and acetic acid, is converted into aniline by the influence of hydrogen gas, in what is termed the nascent state, or the peculiar condition in which it is when being liberated from a compound.

This hydrogen unites with the oxygen of nitrobenzol and removes it as water, and at the same time two atoms of hydrogen combine with the deoxygenated nitrobenzol, forming aniline.

Nitrobenzol. Aniline.

Having now seen the various operations which require to be performed for the production of aniline from coal-tar, we are prepared for the consideration of its coloured derivatives. We will, therefore, commence at once with the first of the coal-tar colours, "the mauve dye." I have already given you the history of its discovery; I will now tell you how it is made.

First of all aniline and sulphuric acid, in the proper proportions for the formation of sulphate of aniline, are mixed in a large vat with water, and boiled until perfectly dissolved. Bichromate of potassium is then dissolved in a second large vat. These two solutions, when cold, are mixed in a third and still larger vessel, and allowed to stand one or two days. In this way a large quantity of a fine black precipitate is formed; this is collected upon shallow filters, well washed with water, and then dried. When dry it is a most unpromising sooty-black powder, and contains various products besides the mauve; the most troublesome of these is a brown, resinous product, soluble in most of the solvents of the colouring matter itself.

At first this resinous substance was removed by digestion with coal-tar naphtha previously to the extraction of the colouring matter, which was afterwards effected with methylated spirits of wine, and the solution thus obtained when distilled left the mauve as a fusible bronze-coloured mass.

When digesting the black precipitate with naphtha or strong spirits of wine, the operation had to be performed in closed vessels under pressure or in connection with a condensing arrangement, otherwise large quantities of these valuable solvents would have been lost; and great difficulty was experienced in getting apparatus perfectly tight, on account of the "searching" character of these fluids. Substitutes had also to be found for the ordinary

materials employed by engineers for making good manhole joints, and a number of other matters which are apparently of but small importance, but it is remarkable the amount of difficulty and annoyance they caused. The method of extraction has, however, been materially improved upon by substituting dilute methylated spirits of wine for strong, as this weaker spirit dissolves only a small quantity of resinous matter but all the colouring matter, so that the digestion with coal-tar naphtha is now found unnecessary.

The solution of the colouring matter in dilute spirit is placed in a still and the spirit distilled off, the colouring matter remaining behind in aqueous solution; this is filtered and then precipitated with caustic soda. It is afterwards collected on a filter, washed with water, and drained until of a thick pasty consistence, and, if necessary, dried.

The solid mauve dissolves very freely in spirits of wine, forming an intensely coloured solution; it is also soluble to a small extent in water, but the aqueous solution on cooling forms a kind of jelly.

The formation of the mauve or aniline purple by the action of bichromate of potassium upon sulphate of aniline is a process of oxidation, and since the publication of the original specification at the Patent Office a great number of patents have been taken out for the preparation of this colouring matter, in which the bichromate has been replaced by other oxidising agents, as peroxide of lead, permanganate of potassium, peroxide of manganese, chloride of lime, ferrocyanide of potassium, chloride of copper, &c.; but I need not make any special remarks upon these various processes, as experience has shown that bichromate of potassium and a salt of aniline, the reagents first proposed, possess advantages over all others, and are now nearly universally employed for the preparation of aniline purple. The next best process appears to be that of Dale and Caro, in which chloride of copper is employed.

The affinity of aniline purple for silk or wool is very remarkable; and, if I take some wool, and pass it through a solution of mauve, you will see how rapidly it absorbs it, even from a very dilute solution. Aniline purple is sent into the market in three different conditions—in paste, in solution, and in crystals; but the latter are very rarely employed, as they are very expensive, and do not offer corresponding advantages to the consumer.

The mauve is the most permanent coal-tar purple known, especially with respect to its power of resisting the action of light.

I will now endeavour to give you some idea of the approximate amount of the various products we have considered obtainable from 100 lbs. of coal; and, for this purpose, I have arranged them in the following table, with their respective weights:—

	Lbs.	Oz.
Coal.. .. .	100	0
Coal-tar	10	12
Coal-tar naphtha	0	8½
Benzol	0	2½
Nitrobenzol	0	4½
Aniline	0	2½
Mauve	0	0½

You see the smallness of the amount of colouring-matter obtainable from coal or coal-tar; but there is fortunately one thing which to some extent compensates for this, and that is the wonderful intensity of this colouring-matter. I will illustrate this remarkable fact. I have here a large carboy, containing 9 gallons of water, and will now add to this a solution containing 1 grain of mauve, and illuminate the liquid with the magnesium-lamp; and you see the single grain has coloured this large bulk of water. A gallon of water contains 70,000 grains; therefore 9 gallons contain 630,000 grains. This solution, then, contains only 1 part of mauve to 630,000 of water.

I have now shown you the manifold operations which have to be performed before we can derive the mauve

from coal-tar, and have also mentioned a few of the obstacles which had to be overcome before its manufacture on the large scale could be accomplished. We have thus laid the ground-work of our subject; and, in our next lecture, I hope to tell you a little more about mauve, and then give an account of the many other colouring-matters of which it may be considered the parent.

(To be continued.)

NOTICES OF BOOKS.

Report on the Quality of the Kerosene Oil sold in the Metropolitan District (New York). By C. F. CHANDLER, Ph.D., &c., New York: D. Appleton and Co. 1870.

THIS paper is a report made by the author in his capacity of Chemist to the New York Board of Health, by which he was instructed to investigate the quality of the Kerosene sold in the city and neighbourhood of New York. The author treats of the composition and varieties of petroleum, on the refining of that liquid, on the quality of kerosene oil, and on the processes vaunted for rendering benzine non-explosive, all of which are perfectly worthless; and, next, enters into the details of the investigation of seventy-eight samples of kerosene oil obtained from the same number of retail dealers. Not one of these samples is safe; all samples contained benzine, gasoline, and naphtha to more or less extent; and only one sample (No. 79), also obtained from a retail dealer, was free from these admixtures, and contained only pure burning oil, usually known in this country as paraffin or crystal oil. The reporter next relates a series of experiments made with the view of ascertaining to what temperature the burning oils become heated in the reservoirs of the lamps in which they are used, different kinds of lamps being employed for this purpose. From these experiments we learn that, even while burning for seven hours, the temperature of the oil does not rise to above 90° F., and that, therefore, an oil which does not evolve an explosive vapour below 100°, and does not take fire itself below 110°, is perfectly safe.

The author next touches the subject of legislation on this matter, first quoting, from the British Acts of Parliament, the directions for applying the flashing test to samples of petroleum oil, and afterwards alluding to the Bill before the State Senate of New York, and discussing some points of interest to the inhabitants of that state. Very properly, the author reflects upon the bill as simply to be made applicable to New York and Brooklyn; it is not only against general good policy, but is a downright infringement of a fundamental constitutional principle, to legislate only for a portion of the inhabitants of a state, or even to make so-called Permissive Acts. These are simply a remnant of feudalism which made slaves and serfs of the bulk of the people, inhabiting the same country, and acknowledging the same person as sovereign.

CORRESPONDENCE.

LOSS OF SODIUM IN SODA-WORKS.

To the Editor of the Chemical News.

SIR,—In the "Chemical Notices from Foreign Sources" given in the CHEMICAL NEWS (vol. xxii., p. 21) appears a brief abstract of the results obtained by M. A. Scheurer-Kestner on the "Loss of Sodium Resulting from its Manufacture according to Le Blanc's Process." The results arrived at by this chemist (viz., that the formation of in-

soluble sodic compounds which remain in the lixiviated refuse constitutes a very large item in the total causes of loss, and that the volatilisation of sodium is inappreciable) are, in the main, identical with those formerly obtained by the writer, and published in the *Journal of the Chemical Society* (August, 1867); the results obtained during the manufacture of some 5000 tons of soda-ash being:—

PREVIOUS TO LIXIVIATION.

	Per cent.
Undecomposed sodic sulphate	3.49
Insoluble sodic compounds	5.44
Vapourisation of sodic compounds, &c. ..	1.14

DURING AND AFTER LIXIVIATION.

Soluble alkali left in vat-waste	3.16
Oxidation of sulphide	inappreciable
Leakage and losses during white-ash process	6.56

Total loss 20.24

I am, &c.,

C. R. A. WRIGHT, D.Sc.

Washington Chemical Works, Washington Station,
Durham, July 11th, 1870.

MISCELLANEOUS.

London Institution.—Our readers will be glad to hear that Mr. J. C. Brough has been appointed Librarian and General Superintendent of the above-named institution.

Utility of Lightning Conductors.—The *Moniteur Belge* of the 6th inst. contains the following:—The powder magazine Santo-Spirito, at Venice, containing no less than 300,000 kilos. (fully 300 tons) of gunpowder, was struck by lightning the other day. The electric discharge fortunately fell on the lightning conductor, the platinum point of which was molten and the rod split and twisted, but no other damage was sustained. The quantity of powder present, if exploded, would go far to lay in ruins ten cities of the size of Venice.

Quality of the Gas Supplied to the Metropolis.—Dr. Letheby, the Chief Gas Examiner for the Metropolis, has recently reported to the Corporation and to the Metropolitan Board of Works on the quality of the gas supplied to the Metropolis by the Chartered, the Great Central, and the City of London Gas Companies. The average illuminating power of the gas, when burnt at the rate of five cubic feet per hour from Sugg's improved Argand burner has been as follows:—The common gas of the City Company has been equal to 17.55 standard sperm candles; that of the Chartered Company, at Leadenhall Street, has been 17.44 candles, at Gray's Inn Lane, 16.92 candles, at Arundell Street, Haymarket, 17.14 candles; and that of the Great Central Company, 17.82 candles. The illuminating power of the Cannel gas of the Chartered Company has been 24.44 candles, and of the City Company 28 candles. As regards impurity, Dr. Letheby reports that the gas of all the companies has been constantly free from sulphuretted hydrogen, although the amount of sulphur in other form than the last named, has varied considerably; for while it amounted to an average of only 12.29 grains per 100 cubic feet of the Great Central gas, and 12.71 grains per 100 feet of the Cannel gas from the City Works, it reached to 22.13 grains, 22.39 grains, and 29.65 grains in the gas of the Chartered Company at the three testing stations of Leadenhall Street, Gray's Inn Lane, and Arundell Street. In connection with this important part of the subject, Dr. Letheby reports that the testing of the gas of the several companies for sulphur during the last twelve months has shown how this obnoxious impurity may be influenced by different methods of purification; for in the case of common gas, the

average proportion of sulphur in the gas from the Great Central Works has only been 12.91 grains per 100 cubic feet, whereas in the gas of the Chartered Company it has ranged from 21.41 grains to 28.59 grains per 100 cubic feet—the average for all the stations of that company being 24.77 grains, and of the City Company 19.75 grains. And again, although the average amount of sulphur in the Cannel gas of the City Company has been but 10.29 grains per 100 cubic feet, it has reached to an average of 24.48 grains in that of the Chartered Company. These large differences are, according to Dr. Letheby, entirely owing to the different methods of purification, and he directs attention to it as a matter of great practical importance.

The other impurity, ammonia, has been always absent from the common and the Cannel gas of the City Company, but it has been frequently present in the gas of the other companies, averaging 0.38 of a grain per 100 cubic feet of the Great Central gas, and from 1.87 to 3.68 grains in that of the gas from the different stations of the Chartered Company; in fact, it has exceeded the prescribed amount of 5 grains per 100 cubic feet, on seven occasions in the Chartered gas at Leadenhall Street, and on nine occasions in the same company's gas at Gray's Inn Lane.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, July 4, 1870.

This number opens with a report on the—

Pyramids of Villejuif and Juvisy.—M. Delaunay.—In the year 1670, M. Picard took, as basis of his geodesical triangulation, the nearly straight roadway which joins together the communes of Villejuif and Juvisy, a distance of 3748 toises (1 toise is equal to 6 feet 6 inches English measure). This basis having been verified in 1740, by J. Cassini and A. La Caille, they erected there, at the expense of an old scientific institution, re-modelled afterwards into the Academy of Sciences, two pyramids, which, having become out of repair, have now been restored, and on each is placed a black marble slab, containing, in gilt letters, simply the following inscription (translated):—"Pyramid of Villejuif; northern limit of the geodesical basis of Villejuif to Juvisy. 1670—Picard. 1740—J. Cassini and La Caille. Property of the Academy of Sciences." The inscription on the Juvisy pyramid is similar. Both these monuments are about 10 metres high, and are situated on the side of the carriage road leading from Paris to Fontainebleau. There is a very great deal of scientific interest attached to the basis alluded to, it having been the first work of the kind ever accurately done, and thus the basis of nearly all such measurements.

Kinds of Rocks met with during the Boring of the Tunnel through the Western Alps between Modane and Bardonnèche.—Elie de Beaumont.—A very lengthy paper, accompanied by a catalogue of the specimens of rocks which have been presented to the Academy, and will in future form a most important mineralogical collection; the more so, because the tunnel, usually known as the Mont Cenis tunnel, will be lined over its entire length (12,220 metres) with bricks and tiles, and the rocks will be hid. As may be expected, this paper, by so eminent a geologist and mineralogist, is of very great value.

Answer to the Remarks made by M. H. Sainte-Claire Deville on the Variations of Temperature Produced by the Mixing of Two Liquids.—Dr. Jamin.—And—

Reply to that Memoir by M. H. Sainte-Claire Deville.—We can only give the titles of these polemical discussions between the rival physicists.

Action of Water upon Iron, and of Hydrogen upon Oxide of Iron.—(Third memoir on this subject).—H. Sainte-Claire Deville.—The author resumes the results of his experiments in the following terms:—The increase of the tension of hydrogen formed by the con-

tact of iron and steam, is a continuous phenomenon when the tension of the steam is made to vary progressively without any variation of the temperature of the iron. That the tension of the hydrogen corresponding to an invariable tension of steam, decreases continually when the temperature increases progressively. That the same laws are observed at the inverse phenomenon of the reduction of oxide of iron by hydrogen.

Isomers of Cyanuric Ethers.—Reply to M. S. Cloëz, by Prof. A. W. Hofmann.

Meteorology of the Spring of the Current Year.—M. Chapelas.—The author considers (1) the temperature, (2) the direction of the winds, (3) the moisture, and draws up a series of comparisons, taken from the meteorological records of former years, to elucidate the meteorological conditions of last spring.

On a Property of the Volta Electrical Condenser hitherto Unnoticed.—P. Volpicelli.—An algebraico-physical memoir.

Deluc's Thermometer.—M. Legrand.—A discussion on the precision of a thermometer scale now almost obsolete, so that this paper is of very little interest.

Compressibility and Expansion of Gases.—Dr. Amagat.

Phospho-Platinic Compounds.—P. Schützenberger.—The author states that he has succeeded in isolating the radical of phospho-platinic compounds before alluded to. The radical turns out to be a black-coloured body, insoluble in water and soluble in alcohol; the formula being $\text{Ph}(\text{C}_2\text{H}_3\text{O})_2\text{Pt}$.

Carbonic and Alcoholic Fermentation of Acetate of Soda and Oxalate of Ammonia.—A. Béchamp.—This lengthy memoir is divided into the following sections:—Carbonic and alcoholic fermentation of acetate of soda; carbonic and alcoholic fermentation of oxalate of ammonia; production of alcohol from the elements of air and water. As regards this latter point, the author asserts that he took very pure distilled water, and poured it into a flask, the mouth of which was simply covered by a piece of paper; after having been set aside for some six months, the author has extracted enough alcohol from the water to ignite. He supposes the cause of this phenomenon to be the formation of microzymas, which induced fermentation. Some ammonia and a volatile acid were simultaneously formed.

Climate of the Elsass and the Vosges.—C. Grad.

Observation on an Unequal Production and Difference of Composition of the Milk from the Breasts of the same Woman.—L. Sourdau.—While the quantity of sugar and salts contained in the milk of the two breasts of the same woman does not perceptibly vary, the author has found that the milk of the right breast contains more butter and caseine than that of the left breast, the difference being as much as in the ratio of 9 to 1.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 208, April, 1870.

This number contains the following original memoirs and papers relating to physico-chemical and collateral sciences:—

Report, by M. Tresca, on the System of Water-Wheels Invented by M. Sagebien.—A very important memoir, illustrated by engravings, on this subject, since the inventor has successfully solved the problem of applying usefully low falls, or weak currents of water, so as to become, by means of the wheels arranged by him, fit for very cheap, yet effective, motive power.

Report, by M. Clerget, on an Apparatus wherein a Continuous Jet of Liquid, and a Gradually Increasing or Decreasing Temperature, are Applied to the Cleansing of Linen Fabrics.—Description, illustrated by engravings, of an apparatus invented by M. J. Decoudun, 77, Rue Montreuil, Paris.

Manufacture of Special Kinds of Cast-Iron.—S. Jordan.—The author discusses, at great length, the calorific phenomena produced by the injection of compressed air, steam, or oxygen into a mass of molten iron, from a multiple of jets.

Effervescing Cyder.—MM. Brosse and Lamfrey.—Cyder, it is well known, becomes, when bottled, after being freshly-made and pure, effervescing to a high degree, but then, also, a highly-intoxicating beverage. The authors apply to cyder a preparation (not specified) whereby it becomes effervescent and a pleasant useful beverage which keeps well for any length of time.

Gaize.—J. Desnoyers.—The substance known as gaize, or *Pierre morte*, is a mineral largely met with in the department of the Ardennes, where it forms a deposit of some 100 metres' thickness. Its sp. gr. is 1.48, and it consists, in 100 parts, of—Soluble silica, 44.8; insoluble silica, 42.0; alumina, 5.1; peroxide of iron, 2.5; lime, a trace; hygroscopic and combined water, together, 5.4. It is, on being dug up, quite soft, so that it can be cut with a knife, but becomes hard on drying, and very hard when exposed to red-heat, whereby its specific gravity is reduced to 1.44. This material is essentially a substance capable of withstanding high temperatures; and the author exhibits crucibles made from the gaize, which have been used successfully for melting iron. Dr. La Salveta, the celebrated chemist of the Imperial Porcelain Works, at Sèvres, states that layers of similar material exist in the central parts of France, likewise deposited in the cretaceous formation; he also states that these minerals are of great value for the construction of blast and other furnaces.

Alloy of Cobalt and Manganese.—A. Valenciennes.—The author exhibits, at the meeting of the Society, samples of metallic cobalt and manganese, and alloys thereof, as well as alloys of copper and manganese, which resemble those of copper and tin. The alloys of cobalt

and manganese are not likely ever to become (the author states) objects of general use; but those of manganese and copper possess properties whereby they may become generally employed.

Annales de Chimie et de Physique, June, 1870.

This number contains the following original papers and memoirs:—

Superficial Tension of Liquids, as deduced from Certain Movements which Take Place on their Surface.—G. van der Mensbrugghe.—The concluding portion of this memoir.

Indices of Refraction of Gases and Vapours, and on the Measurement of their Dispersion.—Dr. M. Croullebois.—This lengthy essay is divided into the following chapters:—The history of the subject; description of instruments, illustrated by woodcuts; indices of gases for homogeneous lights; dispersion of gases; first method, and observations thereon; second method; indices of gases in white light; indices of vapours in homogeneous and white lights; dispersion of vapours, method employed, and description of apparatus, illustrated by woodcuts.

Apparatus Arranged for the Demonstration of the Physical Properties of Vapours.—F. da Fonseca Benevides.—This paper cannot be understood without the reproduction of the annexed cut. The contrivance is simple and effective, and suited to demonstrate, experimentally—The laws of the boiling of liquids and absorption of latent heat; the influence of pressure upon the temperature of the boiling liquid; condensation of vapours (steam and others); development of latent heat; relation between pressure and temperature; production of cold by the dilatation of vapours under high pressure; use of steam as motive power; action of the Giffard's injector.

Evaporation of Water and the Decomposition of Carbonic Acid by the Leaves of Plants and Trees.—P. P. Dehérain.—This lengthy memoir, containing a series of results of experiments exhibited in a tabulated form, is divided into the following sections:—History of the subject, method of experimenting; quantity of water evaporated by leaves exposed to sunlight in one hour; influence of light upon the evaporation. The luminous rays which provoke the evaporation also cause the decomposition of the carbonic acid. Rays of light of the same intensity, but different colour, exert different action, as regards the decomposition of carbonic acid and the exhalation of water.

Estimation of Graphite in Carburetted Iron.—M. Boussingault.—The results of the experiments and analyses detailed at length in this paper, may be summarised as follows:—(1) When a carburetted iron is dissolved in chlorhydric acid, the total quantity of the carbon combined with the metal is eliminated, while the free carbon remains mixed with the other substances insoluble in the acid. (2) Since the residue left by a grey cast-iron, treated by hydrochloric acid, contains a portion of the silicium which was combined with the iron in the state of silica, that residue does not contain any graphitoid silicium nor protoxide of silicium; the estimation of the silica in the residue does not represent the whole of the silicium contained in the cast-iron, because a portion of the silica remains in the acid liquid. (3) That the process based upon the difference of combustibility of the combined carbon and graphite is sufficiently exact to estimate the two kinds of carbon obtained by the action of bichloride of mercury upon the carbonaceous residue of cast-iron or steel.

Annalen der Physik und Chemie, von Poggendorff, No. 5, 1870.

This number contains the following original papers and memoirs—

Sound Emitted from Heated Tubes, and on the Oscillation of Air in Pipes of Different Shape.—Dr. C. Sondhauss.

On Chromates.—C. Freese.—The author has studied some of the hitherto less known salts of chromic acid. Among these we notice—Normal chromate of silver: Attention is called to the mode of precipitating this salt, which differs in composition with the concentration of the silver and chromate solution employed; the normal salt contains 65 per cent of silver and 15.83 per cent of chromic acid. A basic chromate of silver does not exist; a bichromate is well known. Chromate of protoxide of mercury, HgCrO_3 , in 100 parts— Hg , 77.49; Cr , 10.11; O , 12.40. Chromate of deutoxide of mercury, 3HgCrO_3 , in 100 parts— Hg , 80.79; Cr , 6.98; O , 12.83. The chromates of copper are treated of at great length, and the subject is to be continued in a following number.

Thermo-Chemical Researches.—J. Thomsen.—The continuation of the author's very lengthy memoir on this subject, this portion treating on the acids of nitrogen, phosphorus, and arsenic.

Continued Researches on Liquid Conductors of Galvanic Electricity.—J. W. Müller.—The first instalment of a lengthy essay on this subject, subdivided as follows:—Introduction and description of method of investigation, illustrated by diagrams; on the tension of liquid conductors in general; the non-dependence of the tension of alkali and acid upon their chemical combination; first general laws of the direction of the current, and of the electro-motive force of the acido-alkaline conductors; tensions of the alkalies and the acid, and of the salts formed by their union; saline solutions at the end of each pair of metals; effect of dilution of saline solution; effect of concentration of saline solution.

Investigation on the Electric Dust Figures (Staubbildungen).—W. von Bezdold.

Laws of the Formation of Kundt's Dust Figure.—T. Karrasch.—These two papers refer to what are sometimes termed Lichtenberg's

figures, but the contents of neither of them are suited for any useful abstraction.

Description of Electrophoric Machine Suitable to Charge Batteries.—P. Riess.—Illustrated with woodcuts.

Measurement of the Absorption of Light by Transparent Media by means of the Spectrum Apparatus.—Dr. C. Vierordt.

Observations on Induction Sparks.—Dr. A. Weinhold.

Annalen der Chemie und Pharmacie, May, 1870.

This number contains the following original memoirs and papers:—

Researches on some of the Derivatives of Cinnamic Acid.—C. Glaser.—Third part of this essay, divided into the following sections:—Phenyl-propionic acid, $\text{C}_9\text{H}_7\text{O}_2$; formation of phenyl-propionic acid from β bromostyrol; formation of phenyl-propionic acid from a bromo-cinnamic acid; constitution of phenyl-propionic acid; formation of acetenyl-benzol from phenyl-propionic acid; formation of acetenyl-benzol from styrol; metallic combinations of acetenyl-benzol and its conversions (diacetenyl-phenyl; synthesis of phenyl-propionic acid); derivatives from styrol; chlorinated styrols; brominated styrols; conclusions and speculative discussions.

On Mercurio-Ditolyl.—E. Dreher and R. Otto.—This compound—

is obtained by the action of sodium-amalgam upon brom-toluol. It is, as crystallised from boiling benzol, a beautifully white body, exhibiting a strong diamond-like lustre, and crystallising in large rhombic-shaped crystals, insoluble in water, difficultly so in alcohol, best in benzol, chloroform, and sulphide of carbon, and fuses at 235° . The authors describe, at length, the action of the haloids, and of nitric, hydrochloric, hydriodic, and sulphuric acid upon this body; and next treat of acetic acid-mercurio-monotolyl—

a white crystalline substance, fusing at 153° ; insoluble in cold, but more soluble in boiling, water; best soluble in alcohol, sulphide of carbon, and benzol. The paper winds up with an account of researches made with the view of preparing mercurio-dibenzyl—

Behaviour of Dibenzyl at a High Temperature.—E. Dreher and R. Otto.—The main fact of interest in this paper is that dibenzyl is split up, by heat, into toluol and toluylene, according to the formula—

Conversion of Thiophenol (Phenyl-Sulphydrate) into Phenyl-Bisulphide.—E. Dreher and R. Otto.—After referring to the different methods of effecting the conversion alluded to, the authors state that this object can also be attained by heating the mercurial compound, $(\text{C}_6\text{H}_5)_2\text{S}_2\text{Hg} = (\text{C}_6\text{H}_5)_2\text{S}_2 + \text{Hg}$.

Two Isomeric Pentachlorbenzols and Bichlorbenzol-Chloride.—R. Otto.

Mercurio-Dinaphthyl.—R. Otto.—This paper is divided into the following sections:—Preparation of mercurio-dinaphthyl; action of iodine upon mercurio-dinaphthyl; mercurio-mononaphthyl-bromide; behaviour of mercurio-mononaphthyl-iodide with nascent hydrogen and sodium-amalgam; formic and butyric acids, mercurio-mononaphthyl.

Sulpho-Toluide.—R. Otto and A. Gruber.—Sulpho-toluide, $\text{C}_7\text{H}_7\text{SO}_2$, is, when obtained in crystalline state from benzol, a solid body, exhibiting klinorhombic-shaped prismatic crystals; fuses at 155° ; insoluble in water, and difficultly soluble in cold alcohol and ether; rather more soluble in boiling alcohol, benzol, and chloroform. When submitted to the action of heat, in small quantities, it is volatile without decomposition. Heated along with concentrated sulphuric acid, it is gradually converted into toluol-sulphuric acid. The authors quote, at length, the various reactions of this body with several reagents, and discuss its constitution.

Acetic Acid Mercurio-Monomethyl and Acetic Acid Mercurio-Monoethyl.—R. Otto.

Preparation of Organic Sulphur Compounds by means of Hyposulphite of Sodium.—R. Otto.—When ethyl-alcohol is heated for twenty hours, in a sealed tube, with a hot concentrated solution of hyposulphite of soda, it is converted into mercaptan. Iodethyl, heated for two hours to 150° , in a sealed tube, is converted into sulphur compounds, and iodide of sodium is formed.

Diamido-Nitrophenylic Acid, a New Derivative from Picric Acid.—P. Griess.

Azobehzol-Sulphuric Acid.—P. Griess.

Ozone and Antozone.—C. Engler and O. Nasse.

Constitution of Arbutine.—H. Schiff.

Action of Hypochlorous Acid upon the Chloride of Allyl.—H. von Geyerfelt.

New Mode of Synthesis of Naphthalin-Carboxylic Acid.—A. Eghis.

New Method of Estimation of Grape Sugar.—K. Knapp.—This method is based upon the fact that an alkaline solution of cyanide of mercury is completely reduced to the metallic state by grape sugar. The method is executed as follows:—10 grms. of pure and dry bichloride of mercury are dissolved in pure distilled water; to this solution are added 100 c.c. of caustic soda solution (sp. gr. 1.145); and, next, as much distilled water is added as will be required to make a bulk of 1000 c.c. A series of experiments made by the author brought to light the fact that 400 milligrams of cyanide of mercury are, when in alkaline and boiling solution, completely reduced to metal by 100 milligrams of pure grape sugar. The titration is done as in Fehling's method—40 c.c. of the alkaline cyanide solution are boiled in a porcelain basin; and the sugar solution (not stronger than about half a per cent) is added until all the mercury is precipitated. In order to test the course of the operation, a single small drop of the fluid is put upon a piece of Swedish filtering paper stretched over the mouth of a small beaker-glass, while the bottom of that glass is covered with rather strong sulphide of ammonium. As long as any cyanide remains undecomposed, a brownish spot will appear. The author states that, with a little practice, even 1-10th c.c. of the above dilute sugar solution can be readily estimated.

Cosmos, June 18, 1870.

Bicoque Insubmersible.—J. Chabassière.—The author describes, under the above title, at great length, a peculiarly-constructed ship, so contrived as to be really incapable of foundering; and, even when knocked to pieces, its component parts (the passengers' cabins) are so constructed as to constitute floating vessels, each separately. Experimental trials with a vessel made according to the author's suggestions are being performed at Algiers.

The Silix (Flints) of the Chalk considered as Living Bodies.—Rev. P. Sun.—The author thinks that the flints of the chalk may be considered as being the work and production of living beings, similar to the coral reefs found in the ocean, and that, after the death of the microzymas (elementary living organisms) present in the flint, the latter becomes what is termed gaize, or dead stone. This view is strongly combated by many eminent geologists of our time.

Scientific Visit to be made to England.—The French Minister of Marine has ordered that a number of select officers, of all grades of the French navy, shall proceed to England, with the view of visiting, not only dockyards, but also all scientific establishments and institutions which are related to, or work for, the benefit of navies (war and mercantile), and to make a report of their proceedings and investigations.

June 25, 1870.

This number does not contain any original papers or matter relating to physico-chemical sciences.

July 2, 1870.

Vintage of Wines.—J. Guyot.—The author's chief aim is to point out, as regards wine, the danger to health of adding to these fluids (as is usually done for the wine intended for exportation), alcohol, to a greater or less extent. The author expatiates upon the fact that all animal and vegetable products, when brought to a state of chemical purity and stability, are unfit to serve as food, and that the wine consumed in the country districts is sedulously left *au naturel*, even if its quality is mediocre. All who are acquainted with wine-growing countries, and the trade there, know very well that, for every special port of shipment (at least, those belonging to one and the same country), wine is purposely (not as an adulteration, but as a necessity which has sprung into use) prepared for such or such port of shipment, and that this essentially consists in the addition of more or less alcohol, and, sometimes, wines previously boiled with sugar for some time. The author observes that, to make a wine keep is to kill it, being a well-known fact that many small wines are only good during their first year of existence, but do not last above a twelvemonth. Such a wine is active; and it is just that activity which makes it a wholesome beverage which neither affects the head nor the stomach.

Proposed Law Concerning the Free Teaching of Higher Sciences.—This paper, too long for any but brief notice, is an evident proof of that pre-eminence which the Frenchmen possess of making laws so as to be brief, readily understood by all, and worded so as not to lead to litigation or difficulties. Of course, from men of the stamp of MM. Guizot, Dumas, Duruy, and others, no one could expect but a highly-efficient plan, which will, undoubtedly, be a great boon to "La Belle France."

Proposal to Decrease the Existing Drought by Accelerating the Melting and Floating-Down of the Ice in the Polar Seas.—V. Prow.—The author seriously proposes to blow up, by means of dynamite, icebergs and ice-fields in such masses, in the Arctic Regions, as to cause the loose ice to float into the Atlantic, and there to cause, by its rapid melting, such a cooling of the atmosphere and sea as to conduce to the formation of rain. The author has certainly never witnessed the almost total inefficiency of both heavy bombardment of ice-dams, or attempts to blow them to fragments by explosions of gunpowder. Some twenty-four years ago, thaw having set in, experiments were made (as had been often done before) to remove, by the means alluded to, ice-dams on the lower Rhine and some of its branches, the removal of which was absolutely required in order to prevent serious inundations and breaking of embankments; but, although directed by

military men of great skill in these matters, these means proved quite ineffective, and it was only by natural causes that the obstruction was removed in time.

Laboratory Accident.—It appears that a pupil of the School of Pharmacy, named Tronçay, was engaged in heating, in a glass tube, a solution of hyposulphite of soda mixed with nitric acid. While trying to smell, at the mouth of the tube, the odour of the sulphurous acid given off, a sudden ebullition of the liquid took place; as a consequence of which, the contents of the tube were forced out at its open end, with the sad result of seriously burning the eyes of the young man occupied with the experiment. Notwithstanding the immediate aid given by a medical man who happened to be at the school at the time, the young man has lost his eyesight.

Statistics of Berlin University.—Without specifying for all faculties, this University now has a professional staff of 165 men, the largest number being engaged with the philosophy faculty (literature and sciences together), which has 26 ordinary and 31 extraordinary professors, and 20 private (graduated) teachers. In addition, there are 3 masters of living languages, and 3 masters for dancing, music, and gymnastics.

A Burning Mountain.—S. Meunier.—The author states that Mount Vuache (Savoie), near Savigny, has been, for a fortnight past, actually burning—that is to say, it is not, as might be, some fire of dry grass, heather, or trees, but the body of the mountain itself is in flame, and emits a dense smoke to such an extent, that a surface of some 800 square metres is red-hot, and so frightens the people who live near, that the true cause has not been ascertained at present. Some think the mountain has become a volcano.

Application of the Ash and Small Coke of Gas-Works for Brick-Making.—O. Wagner.—The author mixes from 10 to 12 parts of the ash and cinders with 1 part of lime, after having first taken care to break up the small pieces of coke, so as to be of no more than about 5 centimetres cubical size. The mass is mixed with some water, and next mixed in a pug-mill, and, after having become stiff enough, formed into bricks by a brick-making machine. The bricks are slowly, but carefully, dried, and are, after drying, fit for use, making very solid walls, while the material is very light, and especially suited for partition walls.

NOTES AND QUERIES.

Cement.—Can any of your correspondents kindly inform me if there is any known cement that will resist boiling nitric acid?—C. H.

Benzol.—Can any one inform me what kind of apparatus is required for testing the percentage of benzol in naphtha, and where to get them and a book of directions how to test it?—A SUBSCRIBER.

Inflammable Liquids.—Can you inform me whether there is any liquid preparation known that will take fire, spontaneously, on coming into contact with water; or whether there are two liquids, by themselves inflammable, but otherwise when brought together?—G. G. M.

Extract of Meat.—Will you kindly inform me how the extract of meat, now being sold under the name of "Liebig's extract," &c., is made? It appears to be a totally different article to anything like the old-fashioned concentrated soup.—THOS. WELLS.

Work on Sulphur.—(Reply to "George Crampton")—You will find in the latest edition of Payen's "Chimie Industrielle" what you desire; but bear in mind that, unless you have fuel at an exceedingly cheap rate, the extraction of sulphur from the substances alluded to does not pay. You can inspect the work alluded to at the Library of the Commissioners of Patents.

Estimating Sulphide and Sulphite of Calcium.—(Reply to "Alkali.")—You cannot mean exactly what this question states. It must be evident that the process of oxidation will certainly result in the formation of sulphate of lime, rather than of sulphite, and there will then be no possibility of estimating what, previous to that oxidation, was already a far more complex mixture of substances than you suppose; and you will readily understand, therefore, that there is no such method as you desire to be informed upon.

TO CORRESPONDENTS.

Chrome Alum.—This is common alum in which chromium takes the place of aluminium.

A Subscriber.—Good ventilation is your only remedy.

Alfred W. Bennett.—We were glad to hear from you.

E. Sonstadt.—Thanks for your communication. We shall be glad to have your complete paper.

George Gore, F.R.S.—We will send you a reply by post.

L'Abbé F. Moigno.—You have doubtless received the parcel ere this. After making the enquiries, we will write to you.

A. H. Church.—Received, with thanks.

The Secretary of the Aeronautical Society of Great Britain is thanked for his communication.

W. H. Walenn.—Next week.

A Subscriber from the first.—The address of Mr. Siemens is 3, Great George Street, Westminster. You will find a complete description of his furnace, and its successful use, in Vol. III. of "A Practical Treatise on Metallurgy," by Crookes and Röhrig, published by Longmans and Co.

The Honourable the Commissioners of Patents, Washington.—We have received, through Mr. B. F. Stevens, the four volumes of your Reports for the year 1867; for which please accept our thanks.

S. E. Phillips.—Your paper shall, if possible, be inserted next week.

THE CHEMICAL NEWS.

VOL. XXII. No. 556.

NOTE ON SOME NEW DERIVATIVES OF ANTHRACENE.

By W. H. PERKIN, F.R.S.

In the latter part of last year, when experimenting upon the production of alizarine from anthracene, I obtained some interesting reactions, which I described in a Patent dated November 17th, 1869. In this note I propose to give a short account of the chemical changes which take place in some of these reactions, leaving the experimental details to a future occasion.

When dichloranthracene is mixed with fuming sulphuric acid, it gradually dissolves, forming a green fluid, which, upon dilution with water, becomes yellow. The product thus obtained contains one, if not two, new acids, viz., disulphodichloranthracenic acid, $C_{14}H_8Cl_2SO_3$, and monosulphodichloranthracenic acid, $C_{14}H_8Cl_2SO_2$. The formula of the former I have well established, but the existence of the latter is not definitely settled.

Disulphodichloranthracenic acid is of a yellow or orange colour, and easily soluble in water. It is remarkable for the great beauty and intensity of its fluorescence when in dilute solutions. It is dibasic, and forms salts of the formula $C_{14}H_6Cl_2M_2SO_3$. Many of these are difficultly soluble in water, and of a yellow or orange colour.

Dibromanthracene likewise dissolves in fuming sulphuric acid, forming a green fluid containing compounds analogous to those obtained from dichloranthracene, and possessing a strong fluorescence when dissolved in water.

The acids obtained from chlorinated or brominated anthracene, when subjected to the action of oxidising agents, part with their chlorine or bromine, exchanging it for oxygen, yielding disulphanthraquinonic acid,* thus:—

Disulphodichloranthracenic acid.

Disulphanthraquinonic acid.

Disulphodibromanthracenic acid.

Disulphanthraquinonic acid.

When oxidising these sulpho-acids, the termination of the operation is easily seen by the solutions losing their fluorescence.

If dichlor- or dibromanthracene be treated with concentrated or fuming sulphuric acid, and the temperature gradually raised, the disulpho-acids are first formed and then decompose, yielding disulphanthraquinonic acid, thus:—

Dichloranthracene.

Disulphodichloranthracenic acid.

Then—

Disulphodichloranthracenic acid.

Disulphanthraquinonic acid.

Dibromanthracene.

Disulphodibromanthracenic acid.

* MM. Graebe and Liebermann have lately corroborated my results, and obtained disulphanthraquinonic acid by heating dichlor- and dibromanthracene with sulphuric acid. They do not, however, seem to have recognised the intermediate part of the reaction, viz., the formation of the dichloro- and dibromo-sulpho-acids of anthracene. (*Ber. d. Chem. Gesellschaft*, July, 1870, p. 639).

Disulphodibromanthracenic acid.

Disulphanthraquinonic acid.

During my experiments I have repeatedly analysed dichloranthracene, and my results agree with those of Graebe and Liebermann, showing that this body is a substitution product of anthracene, and not a product of addition.

Like anthracene, dichloranthracene combines with picric acid, forming a red crystalline product, which, from analysis, appears to consist of $C_{14}H_8Cl_2 \cdot C_6H_3(NO_2)_3O$.

AIR-POLLUTION BY CHEMICAL WORKS.

(Concluded from p. 27.)

AMONG chemical-works, the largest, and those capable of doing most harm to vegetation, are the alkali-works. In these works, soda, in its various forms of ash, carbonate, bicarbonate, crystal, or caustic, is extracted from common salt. Common salt consists of soda in combination with muriatic acid. When it is mixed with sulphuric acid, and heated, muriatic acid is driven off as a gas. In the earlier days of the soda-manufacture, this acid was considered as a waste product, to be got rid of as speedily as possible. The easiest way was to let it pass into the chimney, and thence into the surrounding atmosphere. Complaints were soon made that trees in the neighbourhood were injured. The manufacturer therefore raised his chimney, building it so high that the acid might be carried away to a great distance by the wind, and its effects lost sight of. The result of this effort was not successful. On wet days, the rain passing through the smoke would wash down the acid, and fall in burning drops even at the foot of the chimney; while, on fine days, the smoke would travel farther, and, though much spread out, still powerful for evil, would carry on its destruction over a larger area. A wiser plan was next adopted. By the use of the now-famous Gossage condensing-towers, the acid-vapours were washed out of the smoke, and kept from contaminating the air altogether. Those alkali-manufacturers who carried out this method well sent out scarcely any acid-vapour to damage the farmers' crops. Some of the manufacturers, however, were behindhand in the movement, and, either from want of skill or of enterprise, did not condense their acid-vapours. Of the efficiency of this condensation in individual cases the farmer could not judge; he found that his crops were still damaged, and therefore brought his action as before, possibly to recover from an innocent party. At this point the Legislature stepped in, and, in the Alkali Act of 1863, passed a measure which has worked well in the interests of both the manufacturers and the agriculturists. The Act announces it to be the duty of the manufacturer to condense 95 per cent of the muriatic acid he produces, and fixes a penalty of £50 for each omission, raising the penalty to £100 after the first conviction. Inspectors are appointed, whose duty it is to visit the works from time to time, and ascertain that the provisions of the Act are carried out. It should be noticed that the Legislature, in passing this Act, stepped out of its accustomed course. The common law maxim is that, for every injury a man may receive, he has his remedy against some one: he must, however, receive the injury before he can seek his remedy. But, in this case, as it already has been shown, much injury may be done which has no remedy. Who can replace an oak-tree of 100 years' growth, and restore the waving woods which adorned the hill-side? The law, therefore, here steps in beforehand; and, no sooner does the inspector find that 95 per cent of the acid is not condensed, than he stops the process under the penalties mentioned. The new law

has been found to work very well. It has enforced the condensation of muriatic acid, to the benefit both of the manufacturer himself and of the public. It has protected the agriculturist against the manufacturer, and the manufacturer against the agriculturist. The inspector is received as a friend by both sides; he protects the farmer's interests by enforcing care on the part of the manufacturer, and he protects the manufacturer's interest by proclaiming the extent to which he carries the suppression of noxious vapours. The A&C has had the effect of bringing up the hindermost manufacturer to the rank of the most skilful. Before this legislation took place, many manufacturers condensed a portion of their muriatic acid; now they all condense, not a small portion only, but fully 95 per cent, some, indeed, habitually condense 99 per cent. The manufacturer finds the visits of the inspector an assistance to him in keeping his condensing-apparatus in efficient order; and an amount of acid escaping which would pass unnoticed by the master or his workpeople is detected by the inspector. It should be understood that, to point out leakage of muriatic acid, is to point out waste; for this acid is needed in the manufacture of bleaching-powder and other products. The amount of acid thus saved by the operation of the A&C is very large. One manufacturer sells muriatic acid annually to the amount of £1500—acid which, previous to the passing of the A&C, was sent up the main chimneys of the works, to the destruction of all surrounding vegetation.

It may now be asked, in general terms, Has the Alkali A&C, this somewhat experimental law, succeeded? does it accomplish the work it was intended to do? The reply is that it has done all, and more, than its promoters or those who understood its provisions expected. But probably the public generally are not satisfied: they fail to understand that a law which professes to shield them from muriatic acid cannot also defend them from chlorine, sulphurous acid, sulphide of hydrogen, and the host of nameless gases by which their noses and their gardens are assailed; still less can they understand that an A&C which should prevent the emission of muriatic acid from the chimney of an alkali-works cannot also prevent the escape of the same acid from copper-extracting works, a bottle-factory, or a pottery.

The A&C must, however, not be blamed for omitting to do that which it was never framed to accomplish. Let us be glad that a step has been gained—that one noxious gas has been measured and suppressed.

Some instances have occurred where manufacturers who are not alkali-makers have desired to place their factories under the inspector appointed under the Alkali A&C: their object being first to know if, in his opinion, they were sending out an injurious amount of noxious vapour; then, having diminished it so as to meet with his approval, to gain his advocacy and defence when harassed by their natural enemies the farmers. This has brought a certain amount of volunteer-work on the inspectors, which they have cheerfully borne on account of the obvious good they could accomplish by diminishing, on the one hand, the escape of noxious acids, and preventing litigation on the other.

In districts such as that around St. Helen's, in Lancashire, where alkali-works and copper-smelting works are found together, the copper-smelters look somewhat enviously at the alkali-makers.

Before the passing of the Alkali A&C, the farmers who thought they had suffered loss through the injury of their crops by acid-vapours charged the damage sometimes against the alkali-works and sometimes against the copper-works. Now, however, owing to the improvements which have been made in the alkali-works under the stimulus of the A&C, and supposing the manufacturers to be somewhat protected by it, the landholders direct their attacks exclusively against the copper-smelters. The amounts claimed by each farmer are not always large, but the aggregate has reached £3000 a-year against the six copper-works.

Besides these smaller claims, an important action was lately brought, by the proprietor of an estate three miles from St. Helen's, against a copper-smelter, for damage done to his trees and crops by the smoke from the works. The course the action took so well shows the present working of the law, and indicates, perhaps, the direction in which it could be amended, that it might be well to give some account of it here.

The plaintiff proved he had received damage from smoke coming from the direction of the defendant's works, and alleged that the damage he had sustained was wholly done by them, intimating that if he gained a verdict in the present suit he should apply to the Court of Chancery for an injunction to restrain the carrying on of the works altogether, as, he believed, he would then be free from all damage. In defence, it was pointed out that the defendant's works lay in a straight line between the plaintiff's land and St. Helen's, so that the same wind which brought defendant's smoke would also convey the smoke from a large portion of St. Helen's; and that, in general, as the plaintiff's park was subject to injury from all the factories in the neighbourhood, it was unjust to charge the whole damage upon the defendant.

It will be seen that the following question would at once present itself:—Is it possible to determine the amount of damage which each factory in a district contributes towards the damage done by all?

In other words, if a farmer sustains a loss of £100 through his crops being injured by the accumulated smoke of a manufacturing district, is it possible to set down to each manufacturer the amount which he ought to contribute towards this £100?

Turning to the fifth of Dr. R. Angus Smith's very able reports under the Alkali A&C, we find this question anticipated, and an answer given. Referring to the amount of acid-vapours thrown up with the smoke of factory-chimneys, he says, at page 25:—Now it is easy to estimate this amount; and it is easy to put down to everyone in the district the exact share of guilt, so far as the acid is concerned. . . . Perhaps we may also bring in the element of distance."

In consequence of this, Mr. Alfred E. Fletcher, the Inspector under the Alkali A&C for the district which includes West Lancashire, was asked to apply himself to the question. He had to consider—

1. The distance of each factory from the injured land.
2. The rate at which the increase of distance diminishes the power of the smoke to do damage.
3. The number of days throughout the year on which the wind blows from each point of the compass.
4. The amount of acid-vapour discharged from each factory in a given time.

First, the distances; these are easily measured on the map.

Information on the second point was obtained in the following manner:—At a time when the ground was covered with snow for a week, lines were drawn, in a direction following the wind, from St. Helen's, and from other groups of works, to a distance of two or three miles. At each half-mile a sample of the surface-snow was collected, and brought home for analysis. Also, during a period of rain, collecting vessels were set at regulated distances from a group of works. A determination was then made of the amounts of muriatic and of sulphuric acids collected by the snow and by the rain, and these were compared with the distances at which the samples had been obtained. It was seen that the amounts diminished in even ratio with the increase of distance. Probably a sufficient number of experiments of this nature have not yet been made firmly to establish the law; for the undulations of the ground, the position of trees, and any objects which interfere with the uniform motion of the air, affect the even deposition of the acid-vapours. More experiments, it was said, were about to be undertaken, in order to establish the law on a wider basis. Information on the third point may be usually obtained at some neighbouring observatory. In

the case of St. Helens, the returns of the direction of the wind published at the Liverpool Observatory, on Bidston Hill, were depended on.

Fourthly, the amount of acid-vapour discharged from each factory in a given time can be known by periodical examination of the gases which are passing up the various chimneys of the works. This is already done, as far as the alkali-works are concerned, under the provisions of the Alkali Act. In the cases of copper-smelting works, glass-works, and others where systematic inspection has not been carried on, the amounts of acid-vapour thrown into the air can be calculated from the materials used in the manufacturing processes carried on.

The acid-vapours discharged from the various works in the St. Helens district are:—From ten alkali-works—muriatic acid, sulphuric acid, sulphurous acid, nitrous acid, chlorine, coal-smoke; from nine glass-works—muriatic acid, sulphuric acid, sulphurous acid, vapour of common salt, coal-smoke; from six copper-smelting works—sulphuric acid, sulphurous acid, coal-smoke; from six collieries, six iron-foundries, two soap-works, eight thousand dwelling-houses—coal-smoke; from the Sankey Brook and the heaps of alkali-waste—sulphide of hydrogen.

This is a formidable list; but the amounts of each may be calculated with a very near approach to accuracy, except the last item, the sulphide of hydrogen, which varies continually with the amount of rain-fall, and with the temperature of the air.

Having, then, collected the information as set forth under these four heads, it became merely a question of figures to apply it to the solution of the problem raised in the St. Helens law-suit. A list was made out of the principal factories in the district capable of doing injury to the plaintiff's land. Opposite these was set down the distance of each factory from the land, and, in a parallel column, the amount of acid-vapour thrown up by each. On dividing the figures in the second column by those in the first, numbers were obtained which were proportioned to the share each one had contributed to the total damage done by all to the plaintiff's land.

Further, a method was adopted by Professor Roscoe, of Owen's College, Manchester, which confirmed the accuracy of this calculation.

St. Helens lies, as has been said, three miles from the plaintiff's park, defendant's works being half-way between them.

While the snow lay on the ground last February, the wind blew mainly from the east. Professor Roscoe then took samples of the snow lying three miles west of St. Helens, and also some of that lying a mile and a half west of defendant's works, that is, the same distance to the west as plaintiff's land is to the south-south-east. He found that the proportion of the amount of acid contained in the one to that contained in the other agreed closely with the proportion determined by Mr. Fletcher in the previous calculation. This was given as evidence at the trial; and it appears that the jury acted on the principle here laid down, that a manufacturer should only be called on to pay in proportion to the amount he contributes to the total damage sustained, and that it is possible to ascertain what that amount should be. Since this trial, two other similar cases have been decided by arbitration: in each of them the arbitrator showed, by his award, that he adopted the principles here set forth.

Having now given some account of the working of the Alkali Act, the most recent legislation on the difficult subject of air-pollution, and sketched the action of the law courts when matters of the kind are brought before them, it may be desirable to discuss the course which further legislation should take in the matter.

As regards the present Alkali Act, we would object that, though successful, it is too limited in its application.

Secondly, the onus of carrying out its penal clauses rests on the inspector. We should have a noxious-vapour Act, applicable to every manufacture where injurious gases are thrown off. The duty of the inspector should be

solely to inspect, and to publish the results of his inspection: the public should be the prosecutors.

Let us follow the working of such an Act. In every district, its inspector would from time to time publish a list of the works, together with the amounts of acid or other vapour escaping from them; this would be given either as the amount in 1000 cubic feet of the chimney-gases, or the actual amount by weight of that which escapes per month or per annum. The result of this to the manufacturers would be that they would anxiously consult the published list, and exercise a wholesome rivalry as to who should stand well in it. Moreover, these lists would form the basis for assessment of damages in case of claims made by the neighbouring farmers. A pecuniary stimulus would thus also be given. To the neighbouring farmer or landholder these lists would be invaluable; they would show him where to apply with the best chance of success for compensation for proved loss by noxious vapours, or enable him to apportion his claim among several works, in proportion to their places in the list and their relative distance from his land.

Thus, in place of the goading influence of a few isolated and sudden prosecutions, a gradual pressure onwards would be felt—a constant stimulus to improvement. All chemical manufacturers cannot be embraced in the provisions of an extended Alkali Act until for each separate noxious vapour a process of suppression can be described, and a limit for its working defined; but, with such an arrangement as is here proposed, all noxious vapours, without the task of enumeration, would be at once legislated for. If there are several manufacturers carrying on the same processes in the same district, and one of them, by special ingenuity, discovers some process by which a large portion of the acid-vapour he has hitherto sent away may be condensed, he improves his place in the list, and so enjoys immunity from actions for damage on the part of the farmers. The other manufacturers would obviously be compelled to follow him in the race of improvement. Thus all would be brought up to the rank of the foremost, and there would be a constant impulse to the manufacturer to reduce the noxious emanations from his works within the smallest possible amount.—*Quarterly Journal of Science.*

CHEMICAL TABLES ACCORDING TO THE THEORIES OF MODERN CHEMISTRY.*

By Prof. ALBERT R. LEEDS.

So long as chemistry was in a transition state between the theory of dualistic combination, the electro-chemical theory of Berzelius and his disciples (which reigned with an almost absolute sway during the first half of the present century), and the unitary theory evolved by Gerhardt, Laurent, Dumas, Hofmann, and other illustrious theorists, chemists might reasonably bear with patience the contradictions and perplexities arising from the unsettled condition of the science. In the opposing rush of contending opinions, the old and well-known landmarks had been swept away, the high-roads of thought had been blocked up by the wrecks of abandoned theories, and little else except the original soil—the facts themselves—remained, upon which the theories of modern chemistry might enter and take undisputed possession. The few who cling to their ancient beliefs have ceased to defend them, and only plead the inaptitude of old age, or the bias of early education, in defence of their loyalty.

But, now that the unitary theory has prevailed, it is intolerable that we should be compelled to reason upon and perform the operations of a chemical synthesis or analysis by the formulæ of the old, and compute its numerical results by the data of the new system. Still more so, that

* Communicated by Professor Morton. From advance-sheet of the *Journal of the Franklin Institute.*

we should calculate values for constituents, the bare existence of which has never been demonstrated. As, for example, that we should calculate, from the results of an analysis of felspar, its percentage of potash, soda, lime, magnesia, iron, and silica, when it has not been proven that any of these compounds exist as such in the felspar. To evaluate the potassium, sodium, calcium, magnesium, aluminum, iron, and silicon radicals, and then add the oxygen, sufficient to close the atomic group, is all that our present knowledge admits of.

To obviate these difficulties, the table given at the end of the present memoir was all that was originally conceived of. It was designed to give, in this table, the formulæ and molecular weights of the most important substances, and to adapt it to the ordinary calculus of synthetic and analytical chemistry. But when it became necessary, as a preliminary step in the construction of such a table, to select values for the atomic weights of the elements, a source of great perplexity presented itself. The values given in the most important general works upon chemistry were found, as will be seen by reference to Table II., to exhibit considerable discrepancies, and to differ, not only between wide limits, but also without apparent rule. There was no shorter way of solving these difficulties than to examine the sources from which these numbers for the atomic weights were originally drawn. This has been an arduous task, and has carried me far beyond the scope of the first intention. But the pleasure and instruction derived from the critical study of the classic literature of the subject, has more than repaid the outlay of time and labour.

First in order and importance is the chapter on the "Bestimmung der Atomgewichte der Grundstoffe," which is given by Berzelius in the third volume of the Leipsic edition of his "Lehrbuch der Chemie." His wonderful analytical skill, fertility of invention, close discrimination, and impartial judgment, inspire the chemist with grateful admiration for his great master. The numbers given by Berzelius are taken on the oxygen scale, O = 100. In the table of atomic weights, according to the original observers, I have computed from these numbers their corresponding values on the hydrogen scale, hydrogen being taken as 6·24, the number assigned to it by Berzelius. But in Table III., which I have adopted as a standard, the value of the hydrogen unit on the oxygen scale has been taken as 6·25, in accordance with Dumas; hence, when the atomic weights of Berzelius have been retained, their values have been re-calculated, on the supposition that the hydrogen unit taken on the oxygen scale is 6·25. This will explain the apparent discrepancies between Tables I. and III. Next in importance to the labours of Berzelius were those of Dumas, which will be found in the *Ann. de Chem.* [3], i., 5; viii., 189; and iv., 129. They were undertaken with the purpose of establishing the truth of Prout's law—that the atomic weights of all the elements are multiples by some whole number of that of hydrogen. The numbers which Dumas obtained compelled him to abandon the law of Prout as originally maintained, and induced him to promulgate it again in a modified form. He brought forward the theory that the elements might be divided into three groups; in the first of which he placed those elements whose atomic weights are multiples of the atomic weights of hydrogen; in the second, those whose atomic weights are multiples of 0·5, the atomic weight of hydrogen; in the third, those whose atomic weights are multiples of 0·25, the atomic weight of hydrogen. But, even then, some deviations from the experimental data was requisite to accommodate his observed to his theoretical atomic weights.

Later, a series of researches was undertaken by Stas, and published under the title of "Recherches sur les Rapports Reciproques des Poids Atomiques," in the *Bull. de l'Acad. R. de Belgique* [2], x. (No. 8), 1860. He re-determined the atomic weights of oxygen, chlorine, sulphur, potassium, sodium, silver, and lead with exceeding care, and exhausted the refinements of chemical art in the purification of his

reagents, the variation of his methods, the accuracy of his weighings, and the verification of his results. The differences between the numbers attained by Stas, in a great number of trials for the atomic weight of each of the above-mentioned elements, is less than the differences between the observed atomic weight and the atomic weight which would be required to bring it into conformity with Prout's law. Stas naturally maintained that the atomic weights which he had obtained by unimpeachable experiments should be adopted in opposition to those supported only by theory. It has been said, in reply, that we must not expect to find in chemistry, any more than in botany and zoology, a law of proportion between parts verified in Nature with mathematical exactness, but only a more or less close approximation—a view certainly of great plausibility, and fortified by abundant analogy. At this point the discussion, for lack of proof more decisive on either side, at present rests.

(To be continued).

ON THE ANILINE OR COAL-TAR COLOURS.*

By W. H. PERKIN, F.R.S.

(Continued from p. 33).

Mauve, Magenta, and some of their Derivatives.

You will remember that in my last lecture we went over all the various steps between coal and colour. We saw how coal-tar was produced from coal; how coal-tar, naphtha, and benzol were separated from coal-tar; how nitrobenzol and aniline were made from benzol, and concluded with an account of the preparation of aniline purple, or mauve from aniline. We will now proceed to the study of some of the most remarkable properties of aniline purple.

This colouring matter is sometimes supplied to consumers in a pure and beautifully crystalline condition. This product is found to be a salt of a compound, chemically termed an organic base. This base has been called "mauveine;" it is composed exclusively of carbon, hydrogen, and nitrogen, in the following proportions:—

Mauveine, although the base of aniline purple, when in solution is not of a purple but of a dull violet shade, and in the solid state is a nearly black crystalline powder. The moment, however, mauveine is brought in contact with an acid so as to form a salt, its solution changes to a purple colour. This takes place even with that feeble acid carbonic. I have here a dilute solution of mauveine; you will observe the dull violet colour it possesses, but if my assistant only breathes through it a few moments the carbonic acid of his breath will combine with it, and it will acquire the ordinary colour of aniline purple.

Mauveine is a most powerful chemical body, and will easily decompose ammoniacal salts. This may be readily seen if some mauveine be heated with chloride of ammonium and a little water, when an abundance of ammonia gas will be evolved, which can be distinguished not only by its odour, but by the white fumes it produces with hydrochloric acid.

The salts of mauveine are beautifully crystalline, and possess a splendid green metallic lustre. The crystallised commercial product consists of the acetate. Mauveine possesses one of the peculiar properties of indigo. Indigo, when treated with reducing agents, such as a mixture of sulphate of iron and lime, is rendered nearly colourless and soluble, but this colourless indigo, when subjected to the oxidising influence of the atmosphere, rapidly becomes blue again. I here refer to the indigo vat so much used by dyers. Mauveine, when treated in a similar manner,

* The Cantor lectures, delivered before the Society of Arts.

is also nearly decolourised, changing to a pale brownish yellow fluid, but the moment this is exposed to the air it assumes its original colour far more quickly than indigo. This remarkable fact may be strikingly illustrated by boiling an alcoholic solution of salt of mauveine with a few strips of zinc in a sealed tube from which the air has been previously removed. The dark purple solution will gradually lose its colour, and change to a very pale-yellowish brown shade.

I have a tube containing some aniline purple decolourised in this manner, and now if I open it, the air rushes in and the solution instantly assumes the ordinary purple colour.

Ordinary indigo is quite insoluble in water, and, therefore, its property of becoming soluble, as well as colourless, when treated with reducing agents, is of great practical value, as the dyer, by immersing his goods in this solution of indigo, and then exposing them to the oxidising influence of the air, gets the colouring matter firmly fixed in the fibre of his materials. But as the mauve is always soluble in water, this property has not been found of any practical value.

Aniline purple, when introduced as a dye, being the first colour of its kind, had to encounter many prejudices, and, on account of its peculiar nature, required the adoption of new or modified processes for its application. These difficulties, however, once overcome, its progress was very rapid. At first it was principally employed by the silk dyer and printer, its application to silk being comparatively easy, but it was not used by the calico-printer till a few years afterwards.

I distinctly remember, the first time I induced a calico-printer to make trials of this colour, that the only report I obtained was that it was too dear, and it was not until nearly two years afterwards, when French printers put aniline purple into their patterns, that it began to interest British printers.

It will be seen that to introduce a new coal-tar colour after the mauve was a comparatively simple matter. The difficulty in the manufacture of all the raw materials had been overcome, as well as the obstacles in the way of the practical applications of an aniline colour to the arts.

We will now turn our attention to a colouring matter which has often been confounded with aniline purple. I have designated it as "Runge's blue," as it was first observed by Runge. I have mentioned that Runge, when he first obtained aniline, termed it "kyanol," or blue oil, on account of the blue-coloured solution it gave with chloride of lime.

After discovering the mauve, I naturally made experiments with this coloured product of Runge's, to see if it contained aniline purple, but my experiments answered the inquiry in the negative. A few years afterwards, however, I was puzzled by finding that French manufacturers were beginning to produce aniline purple by the agency of chloride of lime and a salt of aniline; being much occupied at that time, I was unable to look carefully into the matter; and it was not until investigating these apparently opposite results a short time since that I was able to understand them. I will perform Runge's experiments, and for that purpose will take a solution of hydrochlorate of aniline, and add to it a very dilute solution of chloride of lime (taking care not to add too much). The solution is now changing, and getting slightly opaque; by daylight it has an appearance like indigo, but if I render it clear by the addition of alcohol, and place it before the magnesium lamp, it is seen to be of a brilliant colour, and nearly pure blue, quite unlike aniline purple.

I have lately succeeded in obtaining this blue product in the solid condition by treating a solution of hydrochlorate of aniline with a dilute solution of chloride of lime, and precipitating the resulting colouring matter with common salt; it is thus obtained in an impure condition, and may be collected upon a filter; by treatment with cold ether or benzol, a large quantity of brown impurities are separated, the colouring matter being left in the solid

condition. This substance dissolves in alcohol, forming a nearly pure blue solution, and is capable of dyeing silk a blue or blue-violet colour.

An alcoholic solution of Runge's blue behaves with caustic potash quite differently to aniline purple, forming a brownish-red coloured solution instead of a violet. Therefore, there can no longer be any reason for confounding this body with aniline purple, it being entirely different, both in colour and chemical properties. But as this colouring matter is produced by oxidising hydrochlorate of aniline with chloride of lime, how is it that manufacturers have succeeded in preparing aniline purple with the same reagents? This question I find is very easy to answer: the manufacturer has gone a step further and boiled his product. Now, if I take a piece of silk dyed with Runge's blue, and, instead of boiling it, which would wet it, and make it difficult to manipulate, do that which is equivalent—steam it—a very remarkable change takes place—Runge's blue being changed into the mauve. So, here we have cleared up the mystery, and find that by the action of chloride of lime on hydrochlorate of aniline, we first get Runge's blue, and then, by heating this blue we change it into mauve. Runge's blue is a very unstable body, and of no practical value, its alcoholic solution changing into mauve in a day or two. This change takes place directly by boiling.

We must now pass on to another colouring matter, in name well-known to all of you, I mean magenta, also called roseine, fuchsine, aniline red, and various other names. The discovery of this body and its manufacture were strangely dependent upon the source which had been selected for the preparation of aniline for the mauve. Had the aniline contained in coal-tar, or the aniline obtained from indigo, been employed for the preparation of the mauve, instead of that prepared from commercial benzol, magenta and its train of coloured derivatives would, in all probability, have remained unknown to this present day, from the simple fact that magenta cannot be produced from pure aniline, a second body being also required.

You will observe, by reference to the table of coal-tar products, that next to benzol there is a substance named toluol, a substance having a boiling point not very much above that of benzol. On this account toluol is always contained in commercial benzol, and possesses most of its properties. With nitric acid it forms nitrotoluol, very similar to nitrobenzol; with iron and acetic acid it is converted into a base, toluidine, very similar to aniline, except that it is solid instead of liquid, when pure. Therefore, aniline prepared from commercial benzol always contains a little toluidine, and this is the second body requisite for the formation of magenta.

An apparatus for the fractional distillation of coal-tar naphtha has been devised, so that its constituents may be almost completely separated from each other, and thus pure benzol or pure toluol may be obtained.* Having obtained these hydrocarbons, pure aniline and pure toluidine may be prepared and then mixed in the most suitable proportions for manufacturing magenta. This process is not very generally employed, however, but the quality of the mixture of aniline and toluidine is determined by distillation, noting the quantities which come over at different temperatures. The necessity of toluidine as well as aniline for the production of magenta was discovered by Dr. Hofmann, who found that it could not be produced by perfectly pure aniline, nor perfectly pure toluidine, but that a mixture of these two bases yielded it in quantity. Magenta was apparently first observed by Natanson, in 1856, when examining the action of chloride of ethylene on aniline, and afterwards by Dr. Hofmann, in 1858, when studying the action of tetrachloride of carbon on aniline, but industrially the discovery of magenta was made by M. Virguin, of Lyons, in 1859, three years after the mauve. M. Virguin's process con-

* See "Clarke's Specification," June 5th, 1862, No. 1405.

sisted in treating commercial aniline with a fuming liquid, called tetrachloride of tin, and was first carried out by Messrs. Renard Brothers, of Lyons. Since 1859, patents have been taken out for the production of this colouring matter with aniline, and almost all chemicals known, whether capable or incapable of forming magenta. I may mention one process which was extensively employed, and is still used to some extent in Germany, and that is the method of making magenta with commercial aniline and nitrate of mercury. With care this process works very well, and the colouring matter produced is of good quality. When first introduced, magenta prepared by this method was not purified, but sent into the market in a crude form, so that before using it the dyer had to extract it with water. In the preparation of magenta by this process, all the mercury of the nitrate of mercury employed is recovered in the metallic state, but although this process may possess some advantages, yet the use of mercury salts is most undesirable on account of their fearfully deleterious influence upon the workmen.

The process, which has almost superseded all others, is that for the use of arsenic acid, as proposed by Medlock, and patented by him in January, 1860. This patent is notorious for the amount of litigation it has caused, showing that a patentee should not only be a discoverer but a lawyer, and even more, and able to discover precisely how much to claim and disclaim in his patent, and also to arrange his specification so that the intellects of the whole world may not be able to discover a single flaw in his description; and it is a common misfortune to inventors who wish to thoroughly protect themselves to find that they have claimed too much.

The manufacture of magenta, as now carried on, is a very simple process; it is conducted in an apparatus somewhat similar to that represented by fig. 5.

FIG. 5.

This apparatus consists of a large iron pot, *a*, about 4ft. diameter, set in a furnace of brick-work; it is provided with a stirrer, *b*, worked by hand. All the gearing for this stirrer is fixed to the lid, so that stirrer, lid, and all may be lifted away by means of a crane or other suitable apparatus. There is also a bent tube fixed into the lid, and connected to a condensing worm, *d*, by means of a joint, which can be made or broken at pleasure. In preparing magenta, a quantity of aniline, containing about 25 per cent of toluidine, and a nearly-saturated solution of arsenic acid, is introduced into this apparatus, and well mixed by working the stirrer; the proportions of the materials are in about the ratio of 1 of aniline to 1.5 of a 75 per cent solution of arsenic acid. When these are well mixed the fire is lighted. After the product has been heated for some time water begins to distil over, then aniline and water, and lastly nearly pure aniline.

This operation requires some hours for completion, and this is determined by inserting an iron rod, from time to time, and drawing out a portion of the product for examination, as well as by the amount of aniline which distils over. When the heating has been completed, a steam-pipe is introduced into the apparatus, and steam blown through the fused mass; by this means an additional quantity of aniline is separated. The lid is then liberated and lifted, with the stirrer, from the apparatus, and the product left to cool before it is removed. A more elaborate and larger apparatus is sometimes used, which possesses considerable advantages over the smaller one. The iron pot is larger, and is provided with an outlet at the side, which is closed during the operation, and the shaft of the stirrer is hollow (as in the aniline apparatus described last lecture, fig. 4), and worked by steam. When the operation of heating is concluded, steam is blown down the shaft, and after the addition of water the product is boiled and run out of the outlet in the side of the pot; by this arrangement it is unnecessary to disconnect the lid of the apparatus, and the product does not require to be removed by mechanical means, as with the apparatus previously described.

The crude product obtained by heating aniline and arsenic acid, is next transferred to vats, boiled with water, and filtered. Common salt is then added, which precipitates the crude magenta; this is collected and dissolved in boiling water, again filtered, and the solution, on cooling, deposits the colouring matter in the crystalline condition. This, when re-crystallised, constitutes commercial magenta.

(To be continued.)

ON A CONTINUOUS WATER-BATH.*

AN apparatus of this kind, fully meeting all demands upon it, was some time since designed by Prof. Bunsen, who has abundantly stocked his laboratory with these, now, indispensable, which are only excelled for convenience and in saving of time and labour by the well-known filtering-pump. The want of just such a contrivance as this will have been felt by every chemist.

The method he adopts is to maintain a constant water level in a reservoir, which has free communication with one or with any number of the baths. In the accompanying

cut, *A* is the bath in cross section, composed of an outer copper cylinder, through the centre of which runs a small tube of the same material, emerging at the upper end of the cylinder beneath a large flue. In the lower part of the cylinder an ordinary burner is permanently fixed, which heats the bath, and the products of its combustion are thus safely carried off. The upper part of the cylinder is fitted to receive a large funnel, in which the capsules, &c., of various sizes, containing the material to be evaporated are placed, the watery vapour escaping likewise

* Communicated by Dr. W. H. Wahl. From advance sheets of the *Journal of the Franklin Institute*.

under the flue. The lower end of the cylinder is furnished with an outlet upon each side,—one connecting with an open glass tube attached to its side, to indicate the level of the water within, and the other connecting with the reservoir, B.

This, the essential portion of the contrivance (shown in cross section in cut), consists of an outer glass vessel, B, containing water, in which floats the bulbous tube, a; within this again stands a tube, b, open above like a, and containing some mercury. A tightly fitting caoutchouc ring, between the two, holds b in its place, and prevents any communication with a; and lastly, within b is a small tube, c, connecting with the water main, and dipping somewhat into the mercury of tube b. The tube c is held immovable in its place by clamps indicated at d, and does not partake of the up-and-down motion of the tubes a and b, about to be mentioned.

The various parts having now been given in detail, it only remains to consider their operation.

The water in A and B, being in communicating vessels, is at the same level in both; but the instant the flame lowers the level in A, by vapourising its contents, it is restored by the influx of water from B. The loss of water in B would leave less to buoy up the float, which consequently sinks. In the sinking of the float, however, the opening of the tube c, (which is immovable), is left under the pressure of a smaller column of mercury, and when the sinking has reached a certain point, the pressure of water from the main becomes greater than the opposing pressure of the mercury. Water flows from it, bubbles through the metal, fills the tube b, and overflows at e into the reservoir B. The increase of water in this gives increased buoyancy to the float; it rises, the opening of the tube c is plunged deeper into the mercury, the increasing pressure of which prevents further flow from the water main. The original level has now been regained, and equilibrium restored; but only to be destroyed again, by the continued action of the lamp, vapourising the water in A, which brings about the indefinite repetition of the process just described in detail.

The height to which it is desired that the water, in the bath shall stand, can be regulated in various ways; either by loosening the clamps at d, and closing them again, after giving to the opening of tube c a permanently higher or lower position than it had previously occupied, or by adding to or taking from the mercury in b, &c.

It need scarcely be stated that one reservoir can be connected with quite a number of baths, by carrying a water-pipe behind them and allowing a separate tube to lead to each bath. This contrivance is, as its name indicates, entirely automatic. Material can be left upon it over night; or for days together, without requiring the constant attention, replenishing of water, &c., which make the use of the old, time-honoured instrument so often troublesome and delaying.

NOTICES OF BOOKS.

The Manual of Colours and Dye Wares: their Properties, Applications, Valuation, Impurities, and Sophistications. For the use of Dyers, Printers, Drysalts, Brokers, &c. By J. W. SLATER, Author of "The Handbook of Chemical Analysis for Practical Men." London: Lockwood and Co. 217 pp.

THE author of this little volume states that the object of this manual is to furnish, in a brief space, an account of the chemical products and natural wares used in dyeing, printing, and the accessory arts—their properties, their applications, the means of ascertaining their respective values, and of detecting the impurities which may be present.

We have, therefore, a book professing to give accurate

information upon the subjects the author treats of, in alphabetical order, beginning with acetate of iron (so-called black liquor, or pyrolignite of iron), and ending with sulphate of zinc. It is perfectly clear that it is quite impossible to review *seriatim* each, or even many, of the articles contained in this work; but, in order to judge of its contents fairly and in an unbiassed manner, we shall, at random, take some instances, in order to see how far the author has succeeded in his plans.

At page 41, we read—"Carmine.—The finest portion of the colouring matters of cochineal, freed, as far as possible, from impurities, and combined with alumina." Perfectly pure carmine is readily soluble in ammonia, and does not contain alumina at all. The author forgets that the alum used in the preparation of carmine from cochineal serves no other purpose than that of hastening the settling down of the colouring matter, "carmine," which is *not combined*, as comparatively recent researches have taught, with alumina, and does not contain a trace even of that base: The compound of the colouring matter of cochineal with alumina is known as carmine lake. Of "Chinese Green" (*Lo-kao*), we read (page 44)—"A simple green colour, whose nature and origin are still involved in obscurity." The author should have taken more care to study this matter. The nature and origin of this substance are known accurately; but, from the host of information on this subject, which alone would fill more than two numbers of our paper, we need only state here that it is the product of the *Rhamnus utilis*, called, in Chinese language, *hong-pi-lo-chow*; and not only is the preparation of the *lo-kao* well known, but it is even extracted from European plants of the *Rhamnus* tribe. Speaking of "Madder" (page 107), the author says—"The Dutch and Alsatian madders, which are in great request for certain shades, but which do not equal the Avignon qualities, are"—&c. Now this peremptory statement that these madders do not equal the Avignon qualities, is directly at variance with the experience of all those who employ these substances on the large scale, and are well acquainted with their properties, degree of maturity, and proper mode of application; we can, moreover, say that a large number of sound, practical men, in France, regret that, in order to favour the Avignon and *Palud* (not *Palus*, as written by the author) growers of madder-root, the use of Zealand madder is almost prohibited there. Regarding this, no less an authority than M. Girardin (whose views in this respect were fully endorsed by the late celebrated Mr. Walter Crum) says that, when applied at its maximum of maturity, Zealand madder is, in every respect, superior to all others, and the Alsatian is not much behind it. Speaking of "Persian berries," the author says (page 142)—"Some of the berries are large and greenish, whilst others are smaller, brown and wrinkled, the colouring principles in these two kinds being distinct." There are met with in commerce no less than seven different kinds of these berries, the produce of different countries, as well as of different varieties of the same tribe of shrubs; but it is not correct to say that the colouring principles differ according to the varieties of the berries. The coloured glucosides contained in these berries do not vary, unless the berries are too old and turning black, when the colouring principles have undergone an alteration, as has been proved by the labours of MM. Persoz, Gellatly, Ortlieb, Schützenberger, and Bertéche. The statement, therefore, that, as regards the berries, the colour of the large or greenish should be known as *rhamnein* or *chrysorhamnein* is not correct, the author evidently having neglected to consult the papers of the gentlemen just named on this subject. Of "*Safflower*," it is stated (at page 152) that it contains two colouring matters—a yellow, which is worthless, and a red, which is very fine; it is also said (page 153) that the yellow matter is soluble in cold water. The fact is that safflower contains three colouring matters—viz., one yellow, soluble in pure and acidulated water; another yellow matter, only soluble in an alkaline liquid; and,

lastly, the red colouring matter, called carthamic acid or carthamine.

We need not multiply such instances; a thorough and unprejudiced perusal of this book shows it has been written without sufficient care, and without the use of such books as the author speaks of in a somewhat contemptuous tone in his preface. The work certainly contains some good matter, but the whole *ensemble* has been evidently hurriedly compiled and is very ill digested. Such a work might be made to convey precise and correct information; but the present volume, we regret to say, does not do this. As to the purely chemical part, we abstain, purposely, from saying more than this—that the existence of really good books treating on qualitative, as well as quantitative, chemical analysis, renders superfluous what the author has published in these pages. The typographical execution of the book is good, and its index very complete.

Report on the Gas Nuisance in New York. By C. F. CHANDLER, Ph.D., Professor of Analytical and Applied Chemistry, School of Mines, Columbia College. Extract from the Fourth Annual Report of the Metropolitan (viz., Empire City, New York) Board of Health. New York: D. Appleton and Co. 1870.

WE are indebted to Dr. Chandler for having forwarded a copy of this very interesting and elaborate report.

The nuisance, known as gas nuisance, which for a considerable period of time must have been intolerable to those districts of the City of New York situated near the localities from which it arose, is described by the author as having been caused by the exposure to air of the foul lime used in the so-called dry lime process of gas-purification by some of gas companies which supply the illuminating-gas to the city alluded to; and, in the report before us, the Metropolitan Company is the chief delinquent. This company, it appears, did not take the least heed of the complaints made; and, as a consequence, the Metropolitan (New York) Board of Health took vigorous steps to enforce the order made by it, whereby all the gas companies of the said city were compelled so to conduct their operations as to prevent injury to life and health. The Metropolitan Gas Company, instead of complying, commenced a litigation with the Board; and, as a consequence, there was commenced, before magistrates, an inquiry into the whole affair, and witnesses were heard on oath, and the whole question of gas-purification thoroughly gone into. Among the well-known scientific gentlemen summoned to appear and give evidence were—Dr. Chandler, as chemist to the Board of Health before referred to; Prof. B. Silliman, for the Gas Company; Prof. Wurtz, for the same. Prof. Silliman differed in opinion from Dr. Chandler as to the expediency of introducing the so-called iron purification-process, instead of lime; but he stated clearly and unequivocally that the process of purification as conducted by the Metropolitan Company was a nuisance which, by using simple precautions, could be avoided. After a great deal of delay, and the making of excuses of all kinds, the gas company referred to (having spent, in expert fees, counsel fees, &c., some 10,000 dollars) have complied with the order of the Board of Health, and introduced a system of purification which answers the purpose.

The Report before us (about 112 pages in small type, chiefly containing the full evidence given before the Court at New York) contains, as may be imagined, a very large amount of valuable scientific and practical matter relating to the purification of gas and gas manufacture in general; while the very compact and ably-written paper on the methods of gas-purification from Dr. Chandler's pen greatly contributes to make this work an excellent *exposé* of the subject treated of, as carried out in practice.

CORRESPONDENCE.

THE SPECTROSCOPE APPLIED TO THE BESSEMER PROCESS.

To the Editor of the Chemical News.

SIR,—In the third volume of Crookes and Röhrig's "Metallurgy" (which has just come into my hands), I find, on page 721, that, although the authors give me the credit of first proposing (in 1863) to use the spectroscope in the Bessemer process, they state that the actual practical application is due to Professor Lielegg, in 1868.

As it seems to me, the merit of the practical application is rather due to the Styrian iron and steel makers, who adopted, as valuable, the results of Lielegg's experiments—results which are, in fact, identical with those which I made known five years before. I then showed, beyond doubt, that the exact point of decarbonisation can be accurately arrived at by spectrum observations; and I frequently ascertained that this point exactly agreed with that at which the blast is turned off. The English steel-makers were shown in 1863 exactly that which the Styrian makers were taught in 1868. The English appear to think that the point can be detected by the naked eye with a sufficient degree of exactitude; the Styrians prefer to use the spectroscope.—I am, &c.,

HENRY E. ROSCOE.

Owen's College,
Manchester, July 13th, 1870.

ABRIDGMENTS OF SPECIFICATIONS RELATING TO AERONAUTICS.

To the Editor of the Chemical News.

SIR,—As compiler of the "Abridgments of Specifications relating to Aeronautics," I have to express my best thanks for the very favourable critique upon that little work that appeared in the CHEMICAL NEWS (vol. xxii., p. 19).

As the gentlemen that are deputed by the Commissioners of Patents to compile certain series of Abridgments are extraneous to the Patent Office, as they are chosen for their special knowledge of the subjects they undertake, and as their names are annually published in the Commissioners' Report, I was surprised that no recognition of my connection with that work appeared in your notice. I may perhaps be allowed to remark that the publication of the name of an abridger is possibly an act of justice to the public, as well as to himself. I therefore would suggest that you state my connection with that work, and with the introduction thereto, in any way that you may think best.—I am, &c.,

W. H. WALENN.

74, Brecknock Road, N.
July 13th, 1870.

[The compiler's name having only been given to us in writing, we did not feel at liberty to publish it when reviewing the work.—Ed. C. N.]

RUBIDIUM AND CÆSIUM.

To the Editor of the Chemical News.

SIR,—I have found that, so far as my researches on rubidium and cæsium in sea-water and its products depend upon spectroscopic reactions, they are unreliable. In seaweed, as stated, I have found, by analytical methods, these alkalies; and, so far, the work can receive no further confirmation than it has already had. But, as respects the oxalate of calcium thrown down from sea-water, and the spectroscopic reactions of sea-shells and of limestone, I now believe the lines attributed to rubidium and cæsium

to be due to calcium and to strontium respectively. It is curious, and may, perhaps, partly excuse me, that the trace of strontium, at the most, that can be supposed to be contained in sea-water and in shells should, when so combined, give *only* the line belonging to strontium marked *delta* in the maps, and therefore the fourth in order of intensity; but my further experiments leave me no room to doubt but it is so. This line, in my instrument, is not distinguishable from the blue line given by an impure compound of casium, no more than is the blue calcium line from the most characteristic of the rubidium lines. So far as I trusted to the spectroscope alone, so far I was deceived; but what was done independently of the spectroscope remains true.—I am, &c.,

E. SONSTADT.

Ramsey, Isle of Man,
July 18th, 1870.

MR. BESWICK AND SWEDENBORG.

To the Editor of the Chemical News.

SIR,—Mr. Beswick leads us to a mare's nest. That a certain quantity of dry salt disappears in water without increasing the bulk of the liquid is a very ancient observation. How could a fact at once so curious and obvious escape even a housewife's eye? The familiar anecdote will be remembered of King Charles II. testing the wits of a party of philosophers by requiring of them the reason why a fish immersed in a bucket full of water did not cause the water to overflow. Forthwith, several began to devise explanations, until one, shrewder than his fellows, suggested whether, indeed, a fish behaved like salt under the circumstances!

Swedenborg's assertion that "the saline particle fits the convexity of the watery particles," and "is constantly attended by six aqueous globules," may be true, or may not. The chances are many against its truth; for such wanton fancies are rarely, if ever, verified by experience. At the time Swedenborg wrote (1721), mechanical or geometrical chemistry was in high vogue, and his conjectures would be regarded as perfectly legitimate. Lemery, a *savant* of great celebrity, contributed, in 1711, an elaborate paper to the Memoirs of the French Academy, wherein he argued that a fluid which dissolves a solid does so by pointed particles, which enter into pores of corresponding shapes and sizes in the solid. Thus nitric acid dissolves iron and copper, but not gold; because they have wide and numerous pores, and gold has not. How men had patience for such soothsaying is almost inconceivable at this day. Possibly we are quite as foolish in other ways, as posterity will in due course discover.

Dalton extended the observation of the behaviour of chloride of sodium in water over the whole series of salts with which he was acquainted. His assertion that the initial fact of his investigation was new to him is surprising, and that in its scope, as completed by him, it was "the greatest discovery that he knew of, next to the atomic theory," scarcely less so. We must remember, however, that Dalton's general information was not extensive. He was content to be ignorant of many things, that he might know a few thoroughly. He used to say he could carry all his books on his back. Moreover, in 1840, his well-worn brain was giving way, and he was writing under the exasperation of the rejection of his papers by the Royal Society.

No man holds Swedenborg's merits and memory in deeper reverence than I do, but for that reason fictitious claims advanced in his name affect me with shame and dismay. They only serve to perpetuate the prejudices against him, which I sorrowfully find to be almost insuperable.—I am, &c.

WILLIAM WHITE.

30, Thurlow Road, Hampstead,
July 18th, 1870.

MISCELLANEOUS.

The Hall Testimonial.—On Thursday evening, the 14th inst., a large attendance of former pupils and friends of Mr. Thomas Hall, B.A., F.C.S., assembled at the City of London School, for the purpose of presenting that gentleman with a handsome testimonial, in recognition of his past services as Lecturer on Chemistry and Experimental Physics in that establishment. For the space of twenty-one years (since March, 1847) Mr. Hall had held this post, and successfully directed the studies of a large number of pupils, some of whom have, in consequence, acquired great distinction in the pursuit of science; and his retirement from the school was deemed a fitting occasion for presenting him with a testimonial, subscribed for last year, but only now handed to him, by reason of his compulsory absence from this country on account of ill health. The testimonial took the form of a handsome silver casket and purse of 200 guineas, and was presented by the late head master, the Rev. G. F. W. Mortimer, D.D., Canon of St. Paul's, who took occasion to testify to the successful results of Mr. Hall's teaching, and referred to a recent instance in which he had the satisfaction of presiding, at Barnard Castle, when as many as forty-eight prizes and certificates were bestowed by the Department of Science and Art on the pupils of a gentleman who was himself instructed by Mr. Hall at the City of London School. After Mr. Hall had replied, the present head master (Rev. Edwin Abbot, M.A.), Mr. W. H. Perkin, Mr. J. Spiller, Mr. E. Ryder Cook (Treasurer), and the Hon. Secretary, Mr. J. T. Brown, spoke in complimentary terms on the occasion, and the meeting concluded with a vote of thanks to the Rev. Chairman.

An Improved Method of Producing White Pigments from Lead.—(Letters Patent to J. G. Dale and E. Milner, of Warrington.)—This invention relates to an improved method of manufacturing white-lead, "carbonate of lead," by the action of the soluble acid carbonates of the alkalies on litharge, hydrated oxides of lead, or insoluble basic salts of lead. The patentees propose to carry out their invention in two ways, and when soda is the substance chosen, they proceed—(1) By mixing litharge, hydrated oxides of lead, or insoluble basic salts of lead, with an equivalent of bicarbonate of soda, together with sufficient water to form a stiffish paste. This mixture is ground in a suitable mill, small quantities of water being from time to time added as may be found requisite until the change of the lead bodies into carbonates is complete. The paste is now well washed with water, and the supernatant liquid which contains monocarbonate of soda is separated from the white-lead by filtration, and boiled down to dryness and disposed of as soda-ash; or it may be crystallised; or may be again converted into bicarbonate of soda, by treatment with carbonic acid, and used to convert further quantities of lead oxides, or insoluble basic salts of lead, into carbonates. Instead of grinding, the lead oxides, or insoluble basic salts of lead in a fine state of division, may simply be mixed with bicarbonate of soda and water and left to themselves, when the conversion into carbonates goes on in the same manner, only much more slowly. (2) They mix litharge, hydrated oxides of lead, or basic salts of lead, with caustic soda, monocarbonate of soda, or acid carbonates of soda, and sufficient water to form a stiffish paste. The mixture is now introduced into a suitable closed mill, and during the grinding a stream of carbonic acid gas is passed into it. After conversion of the lead bodies into carbonates, they are washed with water, and the supernatant liquid treated as before described. In carrying out their process by this secondly-described method, the patentees do not bind themselves to any particular proportion of lead oxides and soda, but equivalents of each answer very well. The quantity of the soda salts may, however, be reduced with advantage if found desirable. Grinding may also be dispensed with, by mixing the lead oxides or insoluble basic

salts of lead in a fine state of division with the caustic soda, monocarbonate or acid carbonates of soda, as described, and exposing the mixture in a suitable room to the action of carbonic acid. Artificial heat accelerates the conversion, both in the first and secondly-described operations, but is not essential to their success. The patentees claim the manufacture of carbonate of lead by the action of acid carbonates of the alkalies on litharge, hydrated oxides of lead, and insoluble basic salts of lead, either by direct addition, as described in their first part, or indirectly by the mixture of the lead oxides with the caustic alkalies, or their monocarbonate or acid salts, and their conversion into bicarbonates during the time they are in contact with the litharge, hydrated oxides, or insoluble basic salts of lead.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, July 11, 1870.

This number only contains the record of the frequently-postponed Annual General Public Meeting of the Academy, a meeting devoted to the distribution of the prizes to the authors of the different memoirs and essays written in reply to various questions in science, and found worthy, after careful scrutiny, of the honours the Academy is entitled to bestow. This number also contains the questions for which prizes are proposed to be given in the three ensuing years. From these various items, we abstract those which relate to physico-chemical sciences; in the first place—

Annual Trémont Prize, worth 1100 francs, is given to M. Le Roux, in order further to assist him to continue his researches on thermo-electric currents, and the determination of the indices of refraction of such bodies as do not become volatilised, unless at a very high temperature, such as mercury, sulphur, arsenic, sodium.

The Poncelet Prize (to be given to the author of the best work published on purely mathematical or applied science within the last ten years) is given to Dr. J. R. Mayer, at Heilbronn, for his book on "Die Mechanik der Wärme" (The Mechanical Theory of Heat).

Medals, of the value of 3000 and 2000 francs each, are given to MM. Legros and M. Onimus and M. Cyon, for their important researches on the application of electricity to therapeutics.

Prix Des Arts Insalubres.—(1) To M. Pimont, for the invention of a peculiar kind of cement, a plastic material for covering steam boilers and apparatus wherein steam circulates, thereby to prevent the loss of heat by radiation; (2) to M. Charrière, for apparatus for saving life in cases of fire.

The Cuvier Prize is given to M. Ehrenberg, at Berlin.

The Jecker Prize is given, by a unanimity of votes, to Dr. Friedel, for his researches on organic silicon compounds.

The Montyon Prize is given to M. Arson, for his excellent researches on the flow of gas through great length of pipes.

Among the subjects for which prizes will be given, we notice—Researches to be made on the elasticity of crystallised bodies; on the theory of the rays of the spectrum; for the best work on organic chemistry.

It is usual at this meeting for one of the perpetual secretaries to read an eulogising biography on one of the lately deceased members of the Academy. This year, M. Dumas read such a biography of Theophile-Jules Pelouze, born at Valogne on the 26th of February, 1807. The deceased, a celebrated chemist, was Professor at the Ecole Polytechnique and the Collège de France, President of the Mint Committee, a Member of Council of the Manufactory at Saint Gobain (glass and porcelain works), a Member of the General Municipal Council of Paris, and especially one of the most indefatigable labourers in the wide territory of physico-chemical sciences. Among the large series of his labours, we only allude, in a few words, to his extensive researches on beet-root and the manufacture of sugar therefrom; his researches on hydrocyanic acid, formate of ammonia, and prussic ether; on oceanic ether; on gun-cotton and xyloidine; on fermentation; on the manufacture of glass, and improvements in its composition; on lactic acid and glycerine. The eminent speaker concludes his lengthy discourse

with the following words:—"For forty years, M. Pelouze has been one of the foremost representatives of high science in France; his classical researches and discoveries, and the part taken by him in the reconstruction of organic chemistry, assign to him the rank, which will never be contested, of being one of its most eminent founders. The deceased *savant* was a member of nearly all learned Societies and Institutions of the world."

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 9, 1870.

This number contains the following original papers and memoirs:—

Conversion of Organic Iodides into Bromides.—A. Oppenheim.—The chief point of interest in this paper is that, according to the author's experiments, bibromide of copper, a salt readily and largely soluble in alcohol, is the best and most suitable material to bring about the conversion alluded to. When an alcoholic solution of this bromide is mixed with iodide of allyl, there is formed proto-iodide of copper and brom-allyl—

Iodide of amyl is readily converted into the bromide of allyl, when left for a few hours in contact, at 110°, with an aqueous solution of the bromide of copper.

On Chloral.—C. A. Martius and P. Mendelssohn-Bartholdy.—When equal equivalents of chloral and anhydrous ethylic, methylic, butylic, and amylic alcohol, or even mercaptan, are mixed together, chemical combination of these substances takes place, heat is set free, and the result is the formation of solid compounds, which may be viewed as intermediate trichloroacetals. The ethyl combination boils at 115°–116°, solidifies at 40°; sp. gr. 1.143; soluble in cold water, but far more readily in ether, alcohol, acetic ether, and petroleum essence. The methyl compound boils at 98°. The amyl compound boils at 143°, is solid at 25°; sp. gr. 1.234; is not perceptibly soluble in water, but readily in alcohol and ether, from which solutions it is obtainable in crystalline state.

Chemical Nature of the Hydrate of Chloral.—V. Meyer.—The author says—When the constitution of the hydrate of chloral is expressed by—

it is one of those very rare exceptions to the rule that 2(OH) groups cannot be bound up with the same atom of carbon without producing, at once, an anhydride. The author's researches, as further related in this lengthy paper, are mainly undertaken with the view of establishing the true constitution of the hydrate of chloral, and for this purpose a series of complicated experiments have been made; but the chief result is that the hydrate of chloral is to be viewed as a molecular compound, which, in the state of vapour, consists of a mixture of aqueous vapour and vapour of chloral. The vapour density is 2.86; but, according to the formula—

the density ought to be 5.73.

Relation Existing between the Crystalline Shape and the Chemical Constitution of some Organic Compounds.—P. Groth.—This lengthy, yet very condensed, memoir sets forth that there are certain atoms, and groups of atoms, which are not, as regards their crystalline form, perceptibly affected by substitution of H for other atoms of elements; so that the original crystalline form remains, in the chief, undisturbed.

Some New Reactions of Phenol.—R. Lex.—The author says—Perfectly pure nitric acid (free from any of the lower products of the oxidation of nitrogen) does not, when diluted, act upon an aqueous solution of phenol; while such a solution mixed with a nitrite, and next acidified, yields, even when very dilute, a yellow colouration. If to this solution, an excess of soda is added, a brownish colouration ensues, which is turned into a deep blue by the action of certain reducing substances—as, for instance, sugar, aluminium, zinc. The blue colour thus produced is exceedingly sensitive to the action of acids, carbonic not excepted, which cause the colour to become red; and the colouring matter thus produced is soluble in alcohol and ether. The pure nitro-derivatives of phenol do not produce this phenomenon, which, the author says, is due to the reduction of a peculiar amide body ensuing from the peculiar nitro compound of phenol produced as above alluded to.

Composition of the so-called Wootz, or Indian Steel.—Dr. C. Rammelsberg.—After referring, in a few words, to the ancient methods of procuring iron and steel, and stating that wootz is essentially a cast-steel, the author refers, first, to the analysis of the Indian steel made, in 1819, by the late Messrs. Faraday and Stodart, who stated that the peculiar qualities of this steel were due to silicon and aluminium; next, to the analysis of the same metal (of indisputably genuine origin) made by Dr. Karsten and Dr. Henry, who did not find aluminium at all. The author analysed a portion of a steel bar (Indian steel, certificated for being genuine by the late East Indian Company), and deposited in the Museum of the High Polytechnic School at Berlin; the sp. gr. was found to be 7.822. The author did not find even a trace of aluminium; and, leaving iron aside, the following substances

were found in quantities, per cent.:—Carbon, 0.867; silicium, 0.136; phosphorus, 0.009; sulphur, 0.002.

The Hydrates of Platinic Acid and Platinate of Barium.—H. Topsøe.—The author first refers, at length, to the researches of Drs. Doebereiner, Wittstein, Fremy, and others, on this subject; and next states that the hydrate of platinic acid, air-dried, is a yellowish white powder, readily soluble in solutions of soda and dilute acids, even acetic acid. Heated to 100°, it loses water and becomes iron-rust coloured. Formula, $\text{PtO}_3 + 4\text{H}_2\text{O}$. The acid contains 63.49 per cent of platinum. Platinate of baryta, $\text{BaPtO}_3 + 4\text{H}_2\text{O}$, is, when prepared with excess of baryta, a crystalline compound, containing 43.44 per cent of platinum and 33.67 per cent of baryta.

Action of Chloride of Phosphorus upon Pyruvic Acid.—E. Klimenko.—The author obtained, by this reaction, first, a liquid, boiling at 160°; sp. gr. at 0°, 1.2493; formula, $\text{C}_3\text{H}_5\text{Cl}_2\text{O}_2$. This substance, on being treated with dilute ammonia, yields a solid body, soluble in alcohol, and consisting of $\text{C}_3\text{H}_5\text{Cl}_2\text{NO}$. The author's investigations on this subject are not yet quite finished.

Polymeric Modifications of Aldehyde.—A. Kekulé and Th. Zincke.—The author's lengthy paper treats on paraldehyde and methaldehyde.

Nitrobenzyl-Cyanide and Amidized Benzyl-Cyanide.—E. Czumpelik.

Some Derivatives of Cumic Acid.—E. Czumpelik.

Contribution to the History of a Cymol.—E. Czumpelik.—The length of these three papers, and the fact that the extensive series of lengthy formulae, absolutely required for the proper understanding of the contents, would occupy too much space, forbids anything else than simply the quotation of the titles.

Action of Pentachloride of Phosphorus upon Hyposulphite of Lead.—J. Y. Buchanan.—The author undertook a series of experiments with the view to elucidate the constitution of hyposulphurous acid, but did not quite succeed; he states, however, that hyposulphurous acid cannot be viewed as a sulphuric acid, the hydroxyl of which has been replaced by hydrosulphoxyl.

Contribution to our Knowledge of some kinds of Sugar (Glucose, Cane Sugar, Levulose, Sorbine, and Phloroglucine).—H. Hlasiwetz and J. Haberman.

Evolution of Heat Ensuing on Mixing Water and Sulphuric Acid.—J. Thomsen.

Revue des Cours Scientifiques de la France et de l'Etranger,
June 18, 1870.

This number does not contain any papers or memoirs relating to chemistry, but contains a remarkable paper on—

Vital Power.—Dr. Poelman.—The author states that, in addition to being subjected to the ordinary chemico-physical and mechanical forces, the living body of man is subject to a force which cannot be properly defined, but which supersedes the others, and may be called *intelligence fonctionnelle*.

June 25, 1870.

This number contains a very lengthy report, by Dr. Kékulé, on the—

Labours of the German Chemists in the Past Year.—This paper was read at the meeting of German philosophers and medical men at Insprück, September, last year. The meeting this year will be at Rostock (Mecklenburg-Schwerin).

Spectroscopical Analysis of Blood.—Dr. C. Bernard.—A subdivision of the author's very lengthy and exhaustive lecture on asphyxia by the vapour from incandescent charcoal. This paper is illustrated with woodcuts.

July 2, 1870.

This number contains—

On the Bottom of the Atlantic Ocean.—L. Agassiz.—A lecture, divided into the following sections:—The animal life in the depths of the Gulf Stream; geological antiquity of the existing continents; origin of erratic blocks and loose materials; geology of the bed of the Gulf Stream; madrepore formation of the Gulf of Mexico; submarine and sub-terrestrial basins; the age of the Gulf Stream; limits of the fauna of the Gulf Stream; embryonic evolution of coral, compared with its classification; geological succession, and the depth of its ordinary habitation.

Isomerism (Allotropy) of the Elements.—Prof. Berthelot.—A lecture, treating on sulphur in all its various phases, viz.:—As octahedric, prismatic, amorphous soluble, amorphous insoluble; soft, oily but soluble, oily but insoluble, amorphous insoluble, as obtained from hyposulphites; the absorption of heat by the solution of octahedric sulphur; heat absorbed by the fusion of octahedric sulphur; conversion of octahedric into insoluble sulphur; capability of the different sulphurs of forming compounds; combination preceded by a change of the isomeric state; relation existing between the different states of sulphur and the nature of its compounds; on phosphorus.

We regret that the length of these lectures forbids us to do more than quote the leading points thereof.

July 9, 1870.

This number contains no papers directly relating to chemistry, but we meet here with the concluding lecture of the lengthy series given by Professor C. Bernard, on the—

Asphyxia by Charcoal Vapour.—This portion being divided into the following sections:—Elimination of the oxide of carbon; treatment of the poisoning produced by oxide of carbon; analysis of the gas contained in the blood after inhaling oxide of carbon; is water formed in the organism?

Successor to Professor Magnus.—This lately deceased *savant* is to be succeeded by Professor Helmholtz, from Heidelberg University, who has been elected by the Council of Berlin University a Professor of Physics.

Cosmos, July 9, 1870.

This number does not contain any original paper on matters related to chemistry or collateral sciences. A lengthy paper is devoted to—

The Arènes of Paris, and the Skeletons found there.—C. Brétagne.—To be continued.

And also a paper—

Reply to the Question, From whence do Meteorites come.—S. Meunier.

Revue Hebdomadaire de Chimie, June 9, 1870.

Ammonia Machine.—M. Frot.—Under this title, this and a preceding number contain a description (somewhat vague) of an improvement, or invention, by the author, whereby, instead simply of steam as moving power, a mixture of steam and ammonia gas are applied; but, notwithstanding what is said about the advantages resulting from this arrangement, it is not clearly stated how these advantages are to be gained. Some of our readers will, perhaps, recollect that, many years ago, the vapour of ether and steam, although acting separately, were tried in France instead of steam alone, but with no real success.

Furnace for the Distillation of Bituminous Shales.—MM. Champeaus and Pinard.—By the arrangement described by the authors at length, the carbonaceous matter contained in bituminous shales is partly utilised as fuel, to cause the distillation of oils obtainable from such shales.

Oven for the Smelting of Metals and Ores.—A. Bon.—In main principle, the contrivance described by the author is that in use for glass-blowing and glass-house furnaces, modified in a peculiar manner, so as to smelt metals with greater ease and less loss. The author has obtained a *brevet d'invention* for this furnace, which met the approval of the gentlemen present at the last meeting of the Société d'Encouragement.

Testing Glue.—Dr. Chabrier.—Apart from certain well-known physical properties of good glue, the author states that its goodness (depending on the quantity of pure gelatine it contains) may be tested quantitatively for that substance by the use of nitrate of peroxide of mercury in acidulated (with nitric acid) solution, the solution having been previously titrated with a solution of pure gelatine of known strength.

June 16, 1870.

Analysis of Hops Grown in the Elsass.—C. Mène.—In 100 parts, this material contains—Water, 14.5; essential oil of hops, 0.5; resin, 15.9; tannic acid, 3.02; gum, 11.10; coloured extractive matter, 6.40; salts soluble in water, 0.25; cellulose and other matters insoluble in water and alcohol, 48.33.

Manufacture of Artificial Manure from Native Phosphates.—C. Mène.—This paper describes the preparation of superphosphate manure, but does not contain anything novel on this subject.

June 23, 1870.

Decolouration and Defecation of Saccharine Juices by means of Phosphates and Alumina.—M. Dominique.—The treatment of these juices remains as usual until after the defecation by means of lime; after that, phosphate of ammonia is added, until the juice is slightly alkaline; when tested with red litmus paper, a flocculent precipitate ensues, a mixture of tribasic phosphate of lime and gelatinous hydrate of alumina; this precipitate takes up all the colouring matters and other impurities, leaving the decanted liquid clear and bright. The precipitate is rich, also, in nitrogenous matter, and may be applied as manure, or, treated with sulphuric acid, for the recovering of the phosphoric acid.

Watering the Streets with Saline Solutions instead of with Water only.—Ch. Mène.—The author states that, of the two deliquescent salts which have been applied for this purpose—viz., the chlorides of magnesium and calcium—the last-named suits best, the quantity being adjusted at 250 grms. per square metre. It appears from this paper that, in 1860 and 1863, the Place Bellacour, at Lyon, was (experimentally, and during great heat), watered with a mixture of chloride of calcium and commercial hydrochloric acid, properly diluted in water, the effect being highly appreciated by the inhabitants also on account of the perceptible purification of the air.

Mixture to Render Textile Fabrics Impermeable to Water and Incombustible.—M. Imbert.—Steep the fabrics, first, in an aqueous solution of bichloride of mercury (sp. gr., 1.901); next, in a solution of protochloride of nickel (sp. gr., 1.286); then, in a solution of chloride of zinc (sp. gr., 1.359), followed by dusting over 1 part of chromate of lead; this to be followed by an ammoniacal copper solution, and, lastly, a bath of tartaric acid. The above is exactly reproduced from the French text; but we must observe that, in the first

place, the use of bichloride of mercury, a very poisonous salt also, may affect the colours of dyed fabrics, and that no fabrics, either of wool, silk, linen, or cotton, be they white or dyed, will bear the steeping into the solutions alluded to without injury to the fibre as well as the dye. There are, for the purpose the author desires to attain, simpler and better means.

Bulletin Mensuel de la Société Chimique de Paris, June, 1870.

From the *procès verbaux* of the meetings of this Society, we learn that M. Berthelot related his experiments on the action of phosgen gas (oxychloride of carbon) upon the aromatic hydrocarbons. Among these, the acenaphthen is attacked, the result being the formation of a hydrocarbon less rich in hydrogen, and the evolution of carbonic and hydrochloric acids. Naphthalene is not acted upon by the gas alluded to, even at 230°, neither is benzol at that temperature; but, at 320°, that latter body is strongly acted upon, becoming carbonised, but no chloride of benzoyl is formed. The same speaker next related his researches on trichlorhydrine and bodies isomeric therewith, stating that the trichlorhydrine obtained from glycerine differs from the rest of the isomeric bodies alluded to, by yielding, in the presence of water at 160°, glycerine again. The speaker also pointed out the differences existing between the boiling-points of these isomers and that of their respective derivatives. Dr. Schützenberger related his experiments on the action of sulphuric anhydride upon the chlorides of carbon. With the tetrachloride of carbon, the anhydride yields oxychloride of carbon, COCl_2 , which latter may be readily obtained in liquid state by this mode of preparation. With perchloride of ethylene, C_2Cl_4 , and the anhydride, a strong reaction takes place, but the products are difficult to separate; at 60°, a liquid comes over which, on standing for twenty-four hours, deposits a crystalline compound, $\text{C}_2\text{Cl}_4\text{SO}_2$. The sesquichloride of carbon, C_2Cl_6 , heated with sulphuric anhydride, yields the oxychloride, $\text{C}_2\text{Cl}_4\text{O}$, according to the following equation:—

The same speaker referred to his experiments, whereby chlorine and oxide of carbon are simultaneously made to act upon spongy platinum, the result of which is the formation of a crystalline compound, fusing at 132°; formula, $\text{C}_3\text{O}_4\text{Pt}_2\text{Cl}_4$.

This number contains the following original papers:—

Some Facts relating to the Chemical History of Nitric Acid.—E. Bourgoing.—The chief object of this paper is to communicate the author's experiments on the action of nascent hydrogen upon nitric acid. The results of these experiments, which are related at great length, may be summarised as follows:—The action of nascent hydrogen upon nitric acid, $\text{NO}_2\text{H}_2\text{O}_3$, gives rise to the formation of nitrous acid, deutoxide of nitrogen, nitrogen, and ammonia. The production of nitrous acid is illustrated by $\text{NO}_2\text{H}_2\text{O}_3 + \text{H}_2 = \text{NO} + 3\text{H}_2\text{O}$.

Contribution to the History of the Metallic Benzoates.—F. Sestini.—The author describes, at great length, the following salts:—Benzoate of potassium, $\text{K.C}_6\text{H}_5\text{O}_2 + 3\text{H}_2\text{O}$; and the benzoates of sodium, magnesium, aluminium, zinc, nickel, cobalt, copper, tin, and iron. As regards the latter—viz., the protoxide salt—the author observes that it is erroneously stated, in works on chemistry, that this salt is crystallisable and very soluble. The author states that it is a salt which so rapidly oxidises, that he could not even determine its composition; while, as regards the existence of a crystalline peroxide compound of iron and benzoic acid, the author states that no such salt exists.

Action of Vapours of the Alkali Metals upon Molten Cast-Iron.—C. Girard and J. Poulain.—By keeping the vapours of the alkali metals at a pressure of 5 and 6 atmospheres, and temperatures ranging from 200° to 250°, and introducing into the thus-fused metals molten cast-iron, the authors produce alloys of iron and the alkali metals (potassium or sodium, or even alloys of these two). They describe, at length, the properties of the alloys thus obtained; and state that one of the practical applications of their labours bears upon the production of both steel and cast-iron of good, and even superior quality, from ores otherwise not well suited for smelting. Instead of the direct action of the vapours of sodium or potassium, the same result can be obtained on the large scale by adding, to the iron ore, fuel, and flux, a certain quantity of either chloride of sodium, or carbonate of soda, or the corresponding potash salts.

Action of Oxychloride of Carbon on the Hydride of Oetyl.—MM. De Clermont and Fontaine.—The aim of the authors has been to try whether the general method of synthesis of the volatile fatty acids, as described by T. Harnitz-Harnitzky, is applicable to the higher class of bodies of the acetic and caproic acids series; they therefore experimented with the hydride of oetyl, but found that, notwithstanding the application of all requisite means as regards temperature and pressure (sealed tubes), no action took place between the hydride alluded to and the oxychloride of carbon.

Les Mondes, June 30, 1870.

Experiments made with the Oxyhydrogen-Light at Beauvais (Oise, France).—From a letter to the Reverend editor of the above-named periodical, it appears that a successful series of experiments has been made with the view of testing the qualities of this new mode of artificial light (Tessie du Motay system), previous to its introduction into the city of Beauvais for general daily use; it appears that the oxyhydrogen-light is, in France, fast superseding the ordinary coal-gas. The population of the city alluded to is below 20,000.

Quinquina-Chocolate.—Dr. Heuzé.—The author has succeeded in preparing an extract of Peruvian bark so as to possess no unpleasant

bitter taste, and this is mixed with pure chocolate paste, so as to form readily-portable, and, at the same time, an agreeable, dietetic, medicine. This preparation is (thus it was stated at a meeting of the Central Imperial Society of Agriculture) considered superior to the sulphate of quinine.

New Astronomico-Meteorological Observatory.—The Government of the Argentine Republic, South America, have in view the establishment of an observatory at Cordova (a town of 25,000 inhabitants), at 30½° S. lat.; Dr. B. A. Gould has been appointed as Director and First Astronomer.

Chemical Nomenclature.—Dr. Cap.—The author states that he received from one of the Professors of Chemistry of a Departmental Lyceum, the proposal that, instead of the French names for ice (solid water), water, and steam or aqueous vapour, there should be used, *stearhyde*, or *stearèse d'oxyure d'hydrogenium*; for water, *calorhyde*, or *calorèse d'oxyure d'hydrogenium*; for aqueous vapour or steam, *gazorhyde*, or *gazerèse d'oxyure d'hydrogenium*. In this way the language of science would become more difficult to learn than the science itself.

Bleaching Ivory.—Dr. J. Artus.—The objects made of this substance are first placed into a solution, containing 227 grms. of soda (carbonate) in crystals, and 907 grms. of water. After having been left in this fluid for two days, the ivory objects are well washed in pure water, and then immersed into a solution, composed of 340 grms. of sulphate of soda, and 906 grms. of water, and kept therein for five or six days, after which time there is added to the liquid, yet containing the ivory objects, 28 grms. of hydrochloric acid diluted with 112 grms. of water. After the acid has been added, the vessel (glass or porcelain), containing the liquid and ivory, should be covered, and left standing for from 24 to 36 hours, after which time the ivory is taken out, washed in clean water, and dried. The quantities of ingredients herein specified suffice for 453 grms. of ivory.

NOTES AND QUERIES.

Extract of Meat.—(Reply to Thos. Wells.)—Refer to Dr. Dr. J. von Liebig's paper (*Annalen der Chemie und Pharmacie*, vol. 146, 1868, p. 132).

Benzol.—(Reply to "A Subscriber.")—Refer to the work on Aniline Dyes, by the Editor of this paper. As for apparatus, there are several dealers in these and all articles required by chemists in every large town.

Cement.—(Reply to "C. H.")—In all likelihood, the cement known as zeidellite will answer your purpose. Space forbids us to enter into particulars on this subject, for which we refer you to "Hand und Lehrbuch Der Technologie," von J. R. Wagner, vol. v., p. 210 and following, and to Cooley's "Cyclopedia of Practical Receipts," &c., both of which works you may inspect at the Library of the Commissioners of Patents.

Analysis of Alloys.—I have been analysing some alloys of copper, zinc, and tin, and was surprised at finding as much as 6 per cent of iron in them; but, suspecting the cause to be the breaking away of the teeth of the file, while minutely dividing the alloy before dissolving it, I drilled a hole in parts of the same brass with a carefully-tempered drill, and then found very slight traces of iron, indeed not more than 0.5 per cent in any case, most likely caused by impurity of the zinc used. I merely mention this as showing how careful one need be. The fact of the teeth of the file breaking away is well known to those who use them much, and consequently the cause of the presence of the iron was at once obvious.—T. W.

TO CORRESPONDENTS.

* * Vol. XXI. of THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 11s. 10d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 18s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 18s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxii. commenced on July 1st, and will be complete in twenty-six numbers.

J. Douglas.—This correspondent wishes for particulars of Philipp's carb-oxygen lamp mentioned in our issue of July 9th.

H. Shaker.—If quite purified, it would answer the purpose, but it is a difficult thing to purify.

P. H. M.—The process certainly appears feasible, but we would advise you to experiment on the large scale before taking out a patent.

T. E. Thorpe.—Received.

W. H. Perkins.—Thanks for your communication.

Dr. W. H. Wahl is thanked for his courtesy. The communication will appear.

L'Abbe F. Moigno.—We have forwarded the pamphlets.

Dr. E. H. von Baunhauer.—We are much obliged for the Reports and Programme. We should have much pleasure in acceding to your request, but, unfortunately, many of the earlier numbers of the CHEMICAL NEWS are out of print.

THE CHEMICAL NEWS.

VOL. XXII. No. 557.

ON THE PLATIN-AMMONIA COMPOUNDS.

By S. E. PHILLIPS.

SOME twenty years ago Laurent and Gerhardt endeavoured to clear up an obscure subject by the assumption that there were two platinumum—Platinumum = pt (49); Platinosium = Pt (98).

Hydrochlorate of platinosium was $\text{NH}_2\text{Pt} + \text{HCl}$.

Hydrochlorate of di-platinumum was $\text{N}_2\text{H}_2\text{Pt}_2 + \text{HCl}$.

Hydrochlorate of platinamine was $\text{NH}_2\text{Pt} + 2\text{HCl}$.

As I found the *platinumum* very conveniently chose to appear always in the twin form, I had no difficulty in discarding it, and also forgetting the *platinosium* in the orthodox platinum of that atomic weight. Since then an inverse twin process has given birth to a diatomic platinumum = 197, adopted by Prof. Odling and very widely accepted.

An extended criticism of the above attempt lies before me dated 1850, pointing out the secret involved, of the ureal type of ammonia; showing how simply and clearly old views covered the complex ground taken, and bitterly complaining of the want of discrimination in mixing together simple and definite types with complex or hybrid forms as the basis of sweeping innovations.*

In a late digest, prepared as a study in connection with the recent views of M. Wurtz, I had prepared a condensed outline statement, but I lay this aside in favour of the synopsis furnished by Dr. Odling in his lecture at the Royal Institution, June 8, 1870. My results were tabulated thus;—

Type—AMMONIUM.

$\text{H}_3\text{HN}, \text{O}$. Ammonium.

$\text{H}_3\text{PtN}, \text{Cl}$. The chloride. (Green salt of Magnus).

$\text{H}_3\text{PtN}, \text{O}$. The oxide, { (By heating the hydrate of Reiset's salt).

$\text{H}_3\text{PtN}, \text{Cl} + \text{PtCl}_2$. The chloro-platinate.

$\text{H}_3\text{PtN}, \text{O} + \text{SO}_3$. The sulphate.

$\text{H}_3\text{PtN}, \text{Cl}_2$. The bichloride. { (The chloride of Reiset and Gerhardt).

$\text{H}_3\text{PtN}, \text{O}_2 + 2\text{NO}_3$. The nitrate.

$\text{H}_3\text{PtN}, \text{O}_2 + \text{NO}_5$. The nitrate, { (Under these are comprised some hybrid (?) forms with OCl instead of Cl_2 or O_2 .

$\text{H}_3\text{PtN}, \text{O}_2 + \text{H}_2\text{O}$. The hydrate.

$\text{H}_3\text{PtN}, \text{O}_2 + 2\text{SO}_3$. The sulphate.

Type—ATMONIUM.

$\text{H}_6\text{PtN}_2, \text{O}$. Atmonium.

$\text{H}_6\text{PtN}_2, \text{Cl}$. The chloride. (Reiset's salt).

$\text{H}_6\text{PtN}_2, \text{O}$. The oxide.

$\text{H}_6\text{PtN}_2, \text{S}$. The sulphide. { (Also the iodide, bromide, &c.)

$\text{H}_6\text{PtN}_2, \text{O} + \text{H}_2\text{O}$. The hydrate.

$\text{H}_6\text{PtN}_2, \text{O} + \text{NO}_5$. The nitrate. (Also two carbonates).

$\text{H}_6\text{PtN}_2, \text{O} + \text{SO}_3$. The sulphate.

$\text{H}_6\text{PtN}_2, \text{Cl} + \text{PtCl}_2$. The chloro-platinate. { (The green salt of Magnus?)

$\text{H}_6\text{PtN}_2, \text{Cl}_2$. The bichloride. (Series of M. Gros).

$\text{H}_6\text{PtN}_2, \text{O}_2$. The binoxide.

$\text{H}_6\text{PtN}_2, \text{O}_2 + 2\text{NO}_3$. The binitrate.

$2(\text{H}_6\text{PtN}_2, \text{O}_2) + 3\text{NO}_5$. The sesqui-nitrate.

$\text{H}_6\text{PtN}_2, \text{O} + 2\text{SO}_3$. The bisulphate.

* Dr. Odling says, "The scheme of Gerhardt, though always treated with respect, has never met with general acceptance, and now-a-days, at any rate, is open to very serious objections.

If space permitted, we might go into further details, to show that herein types and constitutions go hand in hand. The exceptional binoxide and bichloride bases are more insoluble and unstable than the more normal types, and the manifest tendency to bi- and sesqui-saltic forms is fairly paralleled in ordinary mineral types. It now only remains to enquire what has been done in this long interregnum; and here we may appropriately introduce the modern views as enunciated by M. Wurtz. He maintains that monatomic metals replace H atom for atom.

Ethylamine. Amidide of sodium. Amidide of potassium.*

But the diatomic metals, copper, cobalt, mercury, &c., replace two atoms of H, and thus correspond with ethylene.

We object to this form of representation. As in the former case, the rule is to notate the ammonia H_3N , and the ammonium $\text{H}_4\text{N}, \text{O}$; so, in the latter, the ammonia, H_6N_2 or H_3N , should not be confused with the atmonium-type, $\text{H}_7\text{N}_2, \text{O}$. Both pairs have their well-marked and distinguishing characteristics; and the question herein is to what extent these oniums may be simply double atoms of the former.

We have the ordinary ammoniacal sulphate of copper, $\text{H}_6\text{CuN}_2, \text{O} + \text{SO}_3$, to which, I believe, the ordinary acetate corresponds; but the oblique rhomboidal prisms of acetate may be $\text{H}_3\text{CuN}, \text{O} + \text{AcO}_3$.

It is notated by M. Wurtz as—

This certainly is a new phase of diatomic fancy—to notate $(\text{H}_6\text{Cu}''\text{N}_2)' (= \text{H}_8\text{N}_2)$, which, with the magic double touch, is supposed, therefore, to combine with 2 atoms of monatomic — (?), $(\text{C}_2\text{H}_3\text{O.O})'$. I know nothing of either entity as such; nor can I admire a system which seems to pride itself in calling PtCl_2 protochloride of platinum, and $(\text{C}_4\text{H}_4)'\text{Cl}_2$ chloride of ethylene. Time was when the consistency of nomenclature was studied; but, now that the requirement has multiplied itself a thousandfold, the rules of common sense are expressly violated.

I have pointed out (CHEMICAL NEWS, vol. xxi., p. 122) that copper evinces a peculiarity of isomeric change, or atomic condensation, which has not been adequately appreciated; and it is not at all improbable that Pt may exhibit the same affection. But it gives no support to diatomic theory; for, in either case, it is clearly manifest that only 1H is replaced.

All the cases given by M. Wurtz of monatomic substitution are in the type of ammonia, while all the cases of diatomic substitution involve the type ammonium; and most or all of them are capable of a simple halving of the atomic weight. If such be invalid, then it is deplorable that no evidence is given *per contra*,—the more so as Bloxam has well pointed out that such a distinction can be exemplified by their different behaviours with reagents, as ably embodied in the researches of Hadow.

Wurtz says that, when ammonia is made to act upon cuprous iodide, $\text{Cu}_2'\text{I}_2$, there are 4 molecules of ammonia

* We have shown that the same principle holds good equally with allied diatomic metals.

retained to a well-defined crystalline compound, $\text{Cu}_2\text{I}_2 + 4\text{H}_3\text{N}$; and, from this, as a basis, is led off another theory—that H_3N may replace 1 atom of H in a complex type of ammonia.

Thus the ordinary sulphate we have referred to becomes—

Now, why is this not a simple iodide of the type so well recognised in the ordinary sulphate alluded to, viz.—

$\text{H}_6\text{CuN}_3\text{I}$, the iodide;

$\text{H}_6\text{CuN}_2\text{O} + \text{SO}_3$, the sulphate.*

It is in this way the ammonium of Reiset's salt is said to contain 4 atoms of N; but it is useless to wade through such numerical guesses of diatomic type without one tittle of chemical evidence or reasoning.

We therefore pass on to the only new fact in this connection, viz., that Hofmann "has proved that methylamine, Me_3N , may unite with bromide of ethylene, $(\text{C}_2\text{H}_4\text{Br}_2)$, to form a bromide. Well, be it so. But surely it is no novelty that 1Br should replace 1H; hence it may be a bromide of Me_3EN , Br where E contains 1Br replacing 1H. Moreover, it is expressly alleged in the context, with a positivity I claim no pretension to in much simpler cases, that $(\text{C}_2\text{H}_4\text{Br})$ does replace 1H.

While ignoring the intelligent researches of Hadow, the extended play in modern memoirs upon monacid and for diatomics, diacid ammonias, is exceedingly questionable.

PROFESSOR ODLING'S SCHEME OF PLATIN-AMMONIA COMPOUNDS.

It is always a pleasure to sit at the feet of this gifted exponent of modern research; and anyone who has heard his unassuming and eloquent lectures at the Royal Institution must feel a pleasurable complacency in seeing that the acceptable mantle of Faraday has fallen upon such able shoulders. But, in this case, our object is rather to criticise a few weak points of a system than to enlarge on the great skill and ability which usually characterise his treatment of subjects.

The first point noticeable involves a continuation of our concluding reference to M. Wurtz—"The double ammonia unites with 2 atoms of HCl to form the hydrochloride." This, in any special sense, is precisely what we cannot see. A simple ammonia must combine with 2 atoms of HCl precisely in the same way that an atmonia or doubly-condensed ammonia does, in both cases to produce the same character of so-called "hydrochloride."

And this principle is equally paramount in the varied metallic or other substitutional forms of either type.

Of course we may numerically represent the simple ammonia as combining with 1 atom of HCl, and the "double ammonia" with 2 atoms; but, in doing so, the former is necessarily a chloride, like sal-ammoniac or chloride of potassium, while the latter is a chlorhydrate and strictly comparable hydrate of potash, $\text{KO} + \text{HO}$, or other hydrates or chlorhydrates. Indeed, this is really implied in the following comparative tabulation:—

Monatomic.	
$\text{KCl} \leftarrow \text{C}_2\text{H}_5(\text{H}_2\text{N})\text{H} \leftarrow \text{Cl}$	$\text{KCl} \leftarrow \text{H}_4\text{N}, \text{Cl}.$
$\text{KHO} \leftarrow \text{C}_2\text{H}_5(\text{H}_2\text{N})\text{H} \leftarrow \text{HO}$	$\text{KO} + \text{HO} \leftarrow \text{H}_4\text{N}_2\text{O} + \text{HO}.$
Diatomic.	
$\text{Ba}''\text{Cl}_2 \leftarrow \text{C}_2\text{H}_4(\text{H}_2\text{N})_2\text{H}_2 \leftarrow \text{Cl}_2$	$\text{Ba}_2\text{Cl}_2 \leftarrow \text{H}_8\text{N}_2\text{Cl}_2.$
$\text{Ba}''(\text{HO})_2 \leftarrow \text{C}_2\text{H}_4(\text{H}_2\text{N})_2\text{H}_2 \leftarrow (\text{HO})_2$	$\text{Ba}_2\text{O}_2 + \text{H}_8\text{N}_2\text{O}_2 + 2\text{HO}.$

* A. Cahours and M. Gal (see CHEMICAL NEWS, vol. xxii., p. 22) find light derivatives from "tri-ethyl phosphine." A prismatic, the city of Bea, is noted, $\text{E}_3\text{PtP}_3\text{Cl}_3$, and said to correspond with hydrogen-light is, N_3Cl . These modern notations are in strict The population of the I have mooted. At 100° C. the salt loses phosphine, (E_3P), and would therefore contain
Quinquina-Choco
preparing an extract o.

In order to lessen the amount of hypothesis in this case, I have, in the second column, preferred to notate the H elements numerically, giving the imaginary double touches their intended value. This well portrays the confusion of M. Wurtz in notating the atmonial type as H_8N_2 , when we know it should be H_7N_2 .

The hypothesis herein is that the simple ammonia combines with 1HCl, and the atmonia with 2HCl. Whereas we have learned throughout a wide area that both normally combine with 1 atom to form the chloride, and with 2 atoms to form the chlorhydrate; and, further, that both in common have their bichloride and binoxide variations.

The Professor notates both simple and double forms as chlorides, and yet speaks of them as "hydrochlorides."

Now, as this cannot be true of the mineral types, and as this tabular comparison is well justified in the context, the conclusion is irresistible that, in both series alike, the first is a chloride and the second is a hydrate.

These may seem small things, and, compared with the practical and profound reasonings (in an eclectic sense) of the learned Professor, I admit their relative smallness; but I hold them in high esteem, and would illustrate their importance by comparison with a contemporary difficulty with an esteemed botanist who is treating of *Proteaceae*, *Nucumetaceae*, and *Folliculares*.

Now, if in a certain great class of vegetables we have an important order of *Proteaceae*, it is clearly wrong to give it a merely family designation; and, if the order be so important and its family and genera so numerous as to require special sub-division, it is clearly confusing to give one of these a family designation, *Nucumetaceae*, and to call another, of equal value or parallel position, *Folliculares*. It is no answer to this objection to say that the generally-understood arrangement of Botany and Zoology into primary divisions—classes, orders, families, genera, and species—may suffice for a popular treatment.

No doubt the rule is in certain circles to (in some measure) despise popular teachers; and truly the task imposed on them is too severe. I am well aware that, as in Chemistry, so in Botany, these little discrepancies (if they be so regarded) are no obstacle to those whose lives are devoted to the departments in question; but to the student, and even the popular teacher, they are great impediments. And I do hold that popular teaching should be correct teaching, and that, except in the degree or amount of minutiae, it is wrong to have two standards of reference.

It will ennoble and exalt the position of our leading great men to have wider audiences; and, if the signs of the times demand a more general appreciation of the beauties and utilities of scientific knowledge, then I say that a double duty is involved. The people must and will respond by some effort on the one side; and the reports of our learned societies must be to some extent divested of a scientific jargon, which is too fatally exclusive for a reasonably wide appreciation.

But, returning to the tabulation, what may we say of the double atoms of oxide and chloride of barium? I prefer to let an accomplished chemist reply; one, moreover, who has walked and worked in the new ways.

Professor Wanklyn says:—

"That the present diatomic formulæ for salts of Ba, Ca, Mg, &c., should have come into general use, and that there should be next to no experimental support for these formulæ, is a most extraordinary thing, and speaks volumes for the depressed state of our chemical conservativeness."

"The reasons in regard to some of these metals were partly some very doubtful deductions drawn from the specific heat of the metals, and mainly from considerations of the vapour-density of certain metallic compounds," &c.

I am indeed surprised and delighted to find the formidable notations of Dr. Odling agreeing so remarkably with my list above, which was projected some twenty years ago,

I now give a parallel comparative list:—

	Proposed scheme.	Old view.
PLATOSAMINE—		
The chloride	$\text{Pt}''(\text{H}_2\text{N})_{2.2}\text{HCl}$	$\text{H}_3\text{PtN}_2\text{Cl}$
„ hydrate	$\text{Pt}''(\text{H}_2\text{N})_{2.2}\text{H}(\text{HO})$	$\text{H}_3\text{PtN}_2\text{O} + \text{HO}$
„ nitrate	$\text{Pt}''(\text{H}_2\text{N})_{2.2}\text{H}(\text{NO}_3)$	$\text{H}_3\text{PtN}_2\text{O} + \text{NO}_5$
AMO-PLATOSAMINE (Reiset's)—		
The chloride	$\text{Pt}''(\text{H}_5\text{N}_2)_{2.2}\text{HCl aq.}$	$\text{H}_6\text{PtN}_2\text{Cl}$
„ hydrate	$\text{Pt}''(\text{H}_5\text{N}_2)_{2.2}\text{H}(\text{HO})$	$\text{H}_6\text{PtN}_2\text{O} + \text{HO}$
„ nitrate	$\text{Pt}''(\text{H}_5\text{N}_2)_{2.2}\text{H}(\text{NO}_3)$	$\text{H}_6\text{PtN}_2\text{O} + \text{NO}_5$
The ethyl-phosphine as notated by M. Cahours and M. Gal.		
		$\text{E}_6\text{PtP}_2\text{Cl}$
PLATINAMINE (Gerhardt's)—		
The chloride	$\text{Cl}_2\text{Pt}'''(\text{H}_2\text{N})_{2.2}\text{HCl}$	$\text{H}_3\text{PtN}_2\text{Cl}_2$
„ hydrate	$\text{Cl}_2\text{Pt}'''(\text{H}_2\text{N})_{2.2}\text{H}(\text{HO})$ (?)	$\text{H}_3\text{PtN}_2\text{OCl} + \text{HO}$
„	$(\text{HO})_2\text{Pt}'''(\text{H}_2\text{N})_{2.2}\text{H}(\text{HO})$	$\text{H}_3\text{PtN}_2\text{O}_2 + 2\text{HO}$
„ nitrate	$\text{OPt}'''(\text{H}_2\text{N})_{2.2}\text{H}(\text{NO}_3)_3\text{aq.}$	$\text{H}_3\text{PtN}_2\text{O}_2 + \text{NO}_5, 3\text{HO}$
„	$(\text{NO}_3)_2\text{Pt}'''(\text{H}_2\text{N})_{2.2}\text{H}(\text{NO}_3)$	$2(\text{H}_3\text{PtN}_2\text{O}_2) + 3\text{NO}_5$
AMO-PLATINAMINE (Gros's)—		
The chloride	$\text{Cl}_2\text{Pt}'''(\text{H}_5\text{N}_2)_{2.2}\text{HCl}$	$\text{H}_6\text{PtN}_2\text{Cl}_2$
„ nitrate	$\text{Cl}_2\text{Pt}'''(\text{H}_5\text{N}_2)_{2.2}\text{H}(\text{NO}_3)$	$\text{H}_6\text{PtN}_2\text{OCl} + \text{NO}_5$
„	$(\text{HO})_2\text{Pt}'''(\text{H}_5\text{N}_2)_{2.2}\text{H}(\text{NO}_3)$	$\text{H}_6\text{PtN}_2\text{O}_2 + \text{NO}_5, \text{HO}$
„	$(\text{NO}_2)_2\text{Pt}'''(\text{H}_5\text{N}_2)_{2.2}\text{H}(\text{NO}_3)$	$\text{H}_6\text{PtN}_2\text{O}_2 + \text{NO}_5, \text{NO}_3$
„	$(\text{NO}_2)_2\text{Pt}'''(\text{H}_5\text{N}_2)_{2.2}\text{HCl}$	$\text{H}_6\text{PtN}_2\text{OCl} + \text{NO}_3$
AMO-DIPLATINAMINE (Raewsky's)—		
The chloride	$\text{Cl}_2\text{OPt}_2'''(\text{H}_5\text{N}_2)_{4.4}\text{HCl}$	
„ nitrate	$\text{Cl}_2\text{OPt}_2'''(\text{H}_5\text{N}_2)_{4.4}\text{H}(\text{NO}_3)\text{aq.}$	
„	$(\text{NO}_3)_2\text{OPt}_2'''(\text{H}_5\text{N}_2)_{4.4}\text{H}(\text{NO}_3)\text{aq.}$	

I have followed herein a uniform system of halving the types given by Dr. Odling, but by no means contend that such is necessarily or in all cases correct.

Bloxam very reasonably contends that the green salt of Magnus, $\text{H}_3\text{PtN}_2\text{Cl}$, should rather be $\text{H}_5\text{PtN}_2\text{Cl} + \text{HCl}$ (or, as in my list, $\text{H}_6\text{PtN}_2\text{Cl} + \text{PtCl}$), that is, a hydrate rather than a chloride.

In this, as in many cases, the probability is great that both forms subsist in analogous cases.

It is most improbable that all platinum substitutions (as in my list) should be mono substitutions; and it is still more improbable that all the series should contain two atoms of Pt, as in Dr. Odling's list. The truth, in all probability, lies between the two extremes; but the pity is, that, while valid bases of discrimination subsist, the matter should be left to the empiricism of individual preference and merely numerical analogies.

Platinum forms no exception to the general facts of substitutional interchange and variation, and the alleged distinctions between mono-, bi-, and tri-atomic elements of substitution may possibly prove to be as fanciful as they are elaborately and ingeniously pourtrayed.

If we instance the radicals of biatomic glycol, or triatomic glycerine, we find that both derived acids are *admittedly* monatomic. And, what is far more to the point, both are derived by an identical process to that which gives acetic acid from alcohol; and, as the latter gives either ethylamine or acetamide, so the former give their corresponding amines or amides—

Ethylamine ($\text{C}_4\text{H}_5\text{H}_2\text{N}$). Acetamide ($\text{C}_4\text{H}_3\text{O}_2\text{H}_2\text{N}$). Glycolamine ($\text{C}_4\text{H}_5\text{O}_2\text{H}_2\text{N}$). Glycolamide ($\text{C}_4\text{H}_3\text{O}_4\text{H}_2\text{N}$). Glyceramine ($\text{C}_6\text{H}_7\text{O}_4\text{H}_2\text{N}$). Glyceramide ($\text{C}_6\text{H}_5\text{O}_6\text{H}_2\text{N}$).

And similarly in corresponding sulpho-acids and other derived and substitutional forms. But, in regard to the platinum case in question, the radicals of carbonic and oxalic acid have a closer bearing on the subject. With these we have—

AMMONIA.	
$(\text{CO})_2\text{H}_2\text{N}$	$(\text{CO})_2\text{H}_2\text{N}$
Carbamide.	Oxamide.
$(\text{CO})_2\text{H}_2\text{NO} + \text{HO}$	$(\text{CO})_2\text{H}_2\text{NO} + \text{HO}$
Carbamic acid.	Oxamic acid.

ATMONIA.	
$(\text{CO})_2\text{H}_4\text{N}_2$	$(\text{CO})_2\text{H}_4\text{N}_2$ (?)
Urea.	
$(\text{CO})_2\text{H}_5\text{N}_2\text{O} + \text{HO}$	$(\text{CO})_2\text{H}_5\text{N}_2\text{O} + \text{HO}$ (?)
The hydrate.	
$(\text{CO})_2\text{H}_5\text{N}_2\text{O} + \text{NO}_5$	$(\text{CO})_2\text{H}_5\text{N}_2\text{O} + \text{NO}_5$
The nitrate.	
&c.	

Let copper replace (CO), and we have another homologous series, where $\text{Cu}(31.5)$ and $\text{Eu}(63)$ equally replace one atom of H to the production of similarly-varied types.

The remarks of Dr. Odling on the platosamine group are very varied and interesting, and, in an eclectic sense, exceedingly cogent and well put.

I also believe in "the parallelism in constitution and properties of the two compounds, and of their corresponding hydrates," and, still further, that neither contains any diatomic element *per se*, or replacement of 2H; but I say nothing of ethylenamine in this connection, being engaged on an extended study of the diatomic hypothesis.

AMO-PLATOSAMINE.

What these are may be seen by a glance at either scheme of notation; they are simple repetitions of the preceding with H_3N superadded—in fact, they are doubly-condensed ammonias, or, as we have called them, atmonias.

PLATINAMINE COMPOUNDS.

In all these, the mode of preparation is instructive; they are forced conditions under the influence of nitric acid or permanganate; and hence the resulting binoxide or bichloride forms of the preceding types, which is especially manifested by the tendency to bi- and sesquialtic types so common in such cases.

It is curious to observe that the three cases selected from Raewsky are, with one little variation in the third instance, precisely double those of the first three of M. Gros's series.

In conclusion, I have merely to observe that this paper has no pretension to any adequate review of the proposed scheme of Dr. Odling, which has the great merit of associating *chemical* with other considerations, and well deserves a higher tribunal.

ON SOLUTIONS: HISTORICAL NOTE.

By CHARLES TOMLINSON, F.R.S.

Those who take any interest in studying the history of science must have felt some surprise at seeing Swedenborg's claim to what has been considered as an important modern discovery in Physics advanced in Prof. Beswick's interesting paper in a recent number of the *CHEMICAL NEWS* (vol. xxii., p. 25).

Swedenborg's reputed discovery that in the solution, say, of a salt in water "the saline particle in the water does not increase the space, but only occupies the void;" or, in other words, "the mere particles of salt cannot at all add to the bulk, but only to the weight, because they occupy the spaces between the aqueous particles," is not, I am inclined to think, so Swedenborgian a proposition as Prof. Beswick supposes. I do not mean to say that earlier writers announced the fact in the same words, but the fact followed, I think, naturally from the theoretical teaching of the previous century.

For example, Descartes (born 1596—died 1650) illustrates the porosity of matter by supposing a number of apples or of bullets, very smooth and round, to be tied up in a net so as to form a compact solid. Whichever way you turn this solid and throw upon it small shot or any similar spherules, they will pass completely through this body by their weight.

Gassendi (born 1592—died 1655), whom Bayle describes as "the greatest philosopher among scholars and the greatest scholar among philosophers," adopts a similar figure to illustrate the porosity of water. He supposes a bushel measure to be filled with wheat; there must then be between the grains certain small spaces void of grains: so among the corpuscles of water or of air, there must be small spaces which, not being filled either with water or air nor with any other body, are absolutely void.

In another place he speaks of silver dissolved by aquafortis and diffused through its little pores.

But the most remarkable passage bearing on the point in hand that I have met with in this very suggestive writer is the following:—"I have long known," he says, "that water can dissolve a certain quantity only of salt, and being once saturated with it the rest remains undissolved. Hence it occurred to me that, the salt being thus reduced to very small particles, there must exist in the water certain small spaces capable of receiving them, which spaces being filled up, solution ceases. It further occurred to me that the corpuscles of salt being cubical might really fill up small spaces which were also cubical. But since the same water could not only dissolve common salt, but also alum, which has an octahedral figure, but also nitre, sal-ammoniac, sugar, and other bodies, which have all different figures, there must, then, also exist in the water octahedral, &c., spaces, so that water being saturated with one of these salts is not prevented from dissolving the others. In effect, my conjecture was right; for having thrown a morsel of alum into water which some days before had been impregnated with common salt, it was dissolved just as if there had been no common salt present; and not only alum, but some other salts that I threw in were dissolved; from which I concluded that there must exist in water a number of insensible spaces of different figures; and I now understood how it was that water saturated with tinctures of rhubarb or of senna or matters ordinarily obtained by infusion is not so saturated with one as to be incapable of taking up another."—(Vol. iii., p. 182*).

It seems to me to follow, from the passage italicised in the above quotation, that the salt with which water is saturated (to use the words of Swedenborg once more), "does not increase the space, but only occupies the void."

Muschenbroek (born 1692—died 1761) published the * I quote from the "Abrégé de la Philosophie de Gassendi," en vii. tomes, par F. Bernier: Lyon, 1684. There is a copy in the Library of the Royal Society. * Presented by the Author, An. 1685." The original Latin of the passage quoted is in *Gas. Phys.*, l. i., sec. i., cap. iii.

first edition of his *Physics* in 1726, and the second in 1734, an English translation of which was published by Colson in 1744. I have not had an opportunity of examining the original, but in the translation, p. 252, the following passage occurs:—"If fluids are composed of spherical or spheroidal corpuscles, they must leave many interstices between them, into which lesser parts can insinuate without the intumescence of the whole mass. Hence salt dissolved in water fills up the interstices, which will be done still more accurately if sugar be then added, and more still by the further addition of alum."

If by *intumescence* is meant "increase in bulk," we have the fact familiarly announced by a well-known investigator in physics in that unconscious manner in which an old and admitted fact is handled. Moreover, in the early part of this treatise there is a good deal of interesting speculation about the shapes of the porous spaces, and calculations as to their magnitudes.

In another once well-known treatise by Clare, "On the Motion of Fluids,"* the well-worn metaphor is used in which water is represented by bullets in a barrel, the interstices between the bullets will contain a great many small shot, "the vacuities of the shot may then be replenished with a certain quantity of sea sand, the interstices of the grains of sand may again be filled with water, and thus may the weight of the barrel be greatly augmented, without increasing the general quantity."† Now this being true with regard to solids is applicable also to fluids. For instance, river water will dissolve a certain quantity of salt, after which it will receive a certain quantity of sugar, and after that a certain quantity of alum, and perhaps other dissoluble bodies, and not increase its first dimensions."

Such is the teaching of all the treatises I have seen about the time when Swedenborg is said to have announced his discovery. It seems to me that the teaching was adopted from Gassendi, which, being nearly a century old, was taken so much as a matter of fact as not to require the special notice it would certainly have met with had it been first pointed out by Swedenborg in 1721-2.

Mr. Beswick supposes that, between the date of Swedenborg's book and Dalton's essay, in 1840, the important fact in question remained unknown, and consequently fruitless. We have already seen that it was not unknown; we have now to show that it was taken up as a good working suggestive fact.

In the memoirs of the Royal Academy of Sciences of Berlin for the year 1750 is a long paper, by Eller, in which are described a number of experiments for determining exactly the quantity of each kind of salt which conceals itself in the water (*qui se cache dans l'eau*) without augmenting the volume, or the vessel in which the operation is conducted becoming fuller. A glass globe of 8 ounces' capacity, with a tube fitted to the neck 10 or 12 inches in length, and 3 lines in internal diameter, was filled, for each observation, with distilled water up to a mark half way up the stem. Each kind of salt was purified and reduced to powder, the temperature being taken in degrees of Réaumur. The 8 ounces of water dissolved the following quantities of the substances named, without any increase in bulk:—

	Drs.	Grs.		Drs.	Grs.
Green vitriol ..	1	10	Seidlitz salt..	1	0
Blue vitriol ..	0	40	Sal de Seignette..	1	0
Ditto, calcined ..	2	0	Soluble tartar ..	2	0
White vitriol ..	1	0	Borax ..	1	0
Alum ..	0	40	Sugar of lead ..	0	40
Ditto, calcined ..	0	50	Refined sugar ..	0	30
Saltpetre, refined ..	1	0	Sal ammoniac ..	1	20
Common salt ..	1	40	Fixed alkali ..	2	0
Cream of tartar ..	0	50	Ammonia Carb. ..	0	40
Glauber's salt ..	1	0	Gum Arabic ..	1	0
Epsom salt ..	1	0	And a number of other solids.		

* My copy is the third edition, bearing the date 1747.
† Query, volume.

All the reasoning in this paper is evidently derived from Gassendi; for example, Mr. Eller says—"No one doubts the porosity of matter; and the preceding phenomena also prove, I think, the existence of interstices among the spherical bullets (*boules*) which form the ultimate elements of the water. I shall not decide whether these pores are triangular, square, pentagonal, or polygonal, so as to assist or refuse entrance to the molecules of the salts which are of different figures. Water, by its intrinsic motion, separates and divides the salt into invisible atoms, probably as small as those of the water, so that they are adapted to thread the pores of the water and become equally distributed among its mass, which holds them suspended and floating by its interior movements, notwithstanding their excess of weight. But the pores of the water being, probably, different among themselves, as the molecules of different salts are, it follows that the homogeneous molecules of one kind of salt can fill only those pores of the water that are adapted to it, while the same water can receive other molecules, whose figures are different from those of the first." Thus, 8 ounces of water saturated with $9\frac{1}{2}$ ounces of green vitriol (at 11° or 12° R.) can still dissolve $1\frac{1}{2}$ ounces of Seidlitz, 2 drachms of refined saltpetre, and 3 ounces of refined sugar; or, the water that has dissolved $2\frac{1}{2}$ ounces of alum can also dissolve 6 drachms of common salt and 1 drachm of Epsom salt.

Mr. Eller also points out (page 92) that mercury will dissolve certain metals without any increase in bulk.

In the *Philosophical Transactions of the Royal Society* for 1770 is a paper by Dr. (afterwards Bishop) Watson, "On the Phenomena Attending the Solution of Salts," from which it appears that the writer failed in attempting to repeat Mr. Eller's experiments.

I have no doubt that, with a little more research, other papers might be found bearing on the point in question. At any rate, it seems scarcely justifiable that so eminent a man as Dalton should, so late as 1840, suppose himself to be the discoverer of these facts, and refer to them as "the greatest discovery I know of next to the atomic theory." Scientific workers and scientific historians form two distinct classes, and the former do not hold the latter in much esteem. In the same way, a first-rate chess player is seldom or never a good problem composer, and as the latter is never the former, he is placed on a low chess level by the Philidors of the clubs.

I ought, perhaps, to add, by way of caution to the student, that the observations of facts above quoted may require a good many *errata*; these are supplied by Messrs. Playfair and Joule (*Phil. Mag.*, xxvii., 1845).

Highgate, N., July 21st, 1870.

ON THE ANILINE OR COAL-TAR COLOURS.*

By W. H. PERKIN, F.R.S.

(Continued from p. 42).

COMMERCIAL magenta consists of brilliant crystals, sometimes half-an-inch in length, having a beautiful golden-green metallic appearance; these dissolve in warm water almost entirely, forming an intense purplish red solution. Dr. Hofmann has carefully studied the chemical nature of magenta, and has found it to consist of the salt of an organic base, which he has called rosaniline. This base may be obtained from the commercial product, by dissolving it in water and boiling it with an alkali, or alkaline earth such as ammonia, potash, or lime; it is thus rendered nearly colourless, and after filtration rosaniline separates from the clear solution, on cooling, in colourless crystals. It is composed of carbon, hydrogen, and nitrogen when anhydrous, but generally contains an equivalent of water also. The anhydrous base has the formula—

This colourless base immediately becomes dark red upon combining with an acid, as I can show you by heating some with acetic acid, when the colour is immediately developed. The magenta produced by heating commercial aniline with nitrate of mercury is the nitrate of rosaniline; that produced with arsenic acid is the arseniate, but in the process of purification this latter salt becomes converted into hydrochlorate, which is the salt most generally found in the market. Other salts are also commercially manufactured, such as the oxalate and acetate, especially when a very pure product is required; these salts are generally prepared from pure rosaniline, by combining it with the required acid, and crystallising from water.

The acetate of rosaniline crystallises in magnificent octahedra, possessing the ordinary golden-green metallic lustre to a very high degree; it is also the most soluble salt of rosaniline known. The affinity of rosaniline salts for animal fibres is very great; it does not, however, resist the action of light nearly to the same extent as the mauve. All the derivatives of rosaniline also possess a very great affinity for animal fibres, in most cases quite equal to that of magenta itself.

When speaking of aniline purple, I showed you that by reducing agents it became colourless, or nearly so, but that the original colour was developed when it was exposed to the oxygen of the air. Salts of rosaniline or magenta are also decolourised by reducing agents, but, unlike aniline purple, the colour is not restored by exposure to the air. Dr. Hofmann has found that in this case a new organic base is produced which he has called leucaniline. This substance differs only from rosaniline in containing an additional quantity of hydrogen. It may be re-converted into rosaniline by oxidising agents such as bichromate of potassium, &c.

There is another very peculiar reaction of rosaniline. This base, when brought in contact with hydrocyanic acid, instead of forming a coloured hydrocyanate of rosaniline, yields a perfectly colourless body, which is not a salt but a base. This remarkable fact was discovered by Dr. Hugo Müller, and he has called this new body hydrocyanrosaniline. We shall have occasion to refer again to this substance and leucaniline.

In the formation of magenta, a second product is obtained, commercially called phosphine. This substance was first introduced by Mr. E. Nicholson. Dr. Hofmann has investigated it, and found it also to contain an organic base, which he has called chrysaniline.

Phosphine or chrysaniline is not capable of being produced at will, and the quantity formed in the manufacture of magenta is variable. In shade it is of rather a yellow orange. This colouring matter differs from rosaniline, the base of magenta, in exactly the opposite direction to leucaniline, containing two atoms less of hydrogen. Leucaniline, rosaniline, and chrysaniline, are thus related:—

The principal use of phosphine is for the formation of a scarlet with magenta. It is not converted into magenta, nor decolourised with reducing agents or hydrocyanic acid, and, therefore, does not seem to be of the same class of colouring matters as rosaniline.

From the residues obtained in the manufacture of magenta three new colours have been obtained by Messrs. Girard and Delaire, but, I am sorry to say, my time will not allow me to enter into the particulars of these products. I believe they have not been commercially introduced as yet.

Magenta is now more used as a source of other colours than as a dye. This has caused its manufacture to be conducted on a very extensive scale, and it is now looked upon by the manufacturer as a raw material much in the same way as aniline was regarded in the early days of aniline purple.

* The Cantor lectures, delivered before the Society of Arts.

We will next consider some of the derivatives of magenta, and the first we will study is aniline blue or bleu de Lyon. If aniline be treated with a salt of rosaniline or magenta, a remarkable change takes place; at first the colour gradually becomes purple, but afterwards gets quite blue, ammonia being evolved at the same time. This peculiar reaction was observed by MM. Girard and Delaire, who found that that this change of colour was due to the formation of a new body, which they termed the bleu de Lyon; intermediate products were likewise obtained, to which we shall refer presently. MM. Girard and Delaire patented their process in January, 1861. This new aniline blue is one of the most important of the artificial colouring matters, and its manufacture has been very much improved upon since its discovery. There are several circumstances which materially influence the beauty of its tint, such as the quality of the aniline and

the particular salt of rosaniline employed in its manufacture. It is found by experience that the aniline should be as pure and free from toluidine as possible, and that the salt of rosaniline should contain a feeble acid, such as the acetate, valerate, oleate, or benzoate; but why the latter is necessary chemists are unable to understand at present. Practically, the various salts of rosaniline required for the manufacture of the blue are not prepared separately, but are produced in the operation by double decomposition, which is simply a process of exchange; thus, if acetate of rosaniline is required, a mixture of hydrochlorate of rosaniline and acetate of sodium is employed; these react on each other, and change into acetate of rosaniline and chloride of sodium.

On the large scale, the process of making aniline blue is carried out in various ways, but many employ the apparatus shown in fig. 6. This apparatus consists of an

FIG. 6.

oil bath, *a*, set in a brick furnace; it has a cover, *b*, perforated with large holes; into these holes are placed small enamelled cast-iron pots, *c*, provided with a flange, on which they rest. These pots will hold from three to five gallons, and are fitted with lids held down with clamps; each lid is provided with a small stuffing-box, through which the rod of a stirrer, *d*, passes. In the lid are also two other perforations; one of these is fitted with a wooden plug, *e*, for the purpose of testing the progress of the operation; the other is connected with a bent, movable tube, *f*, united to a long central main, to collect any aniline vapour which passes over. This main is connected at one end with a worm, *g*, to condense the vapours. The oil bath by which these pots are heated is provided with a thermometer, so that the temperature may be properly regulated. In preparing the blue a mixture of magenta, acetate of sodium and aniline is introduced into the pots, the aniline being employed in excess. When charged, the oil-bath is heated up to 190° C., and kept near that temperature. At first the red colour of the mixture changes slowly, but afterwards with rapidity. The progress of the operation is ascertained by removing the wooden plug, and withdrawing a small quantity of the product upon the end of an iron or glass rod, and it is considered complete when a good blue colour has been obtained; to ascertain this point with precision, considerable experience is necessary. The excess of aniline distils during this operation, and is condensed by the worm, and collected into a suitable receiver, so that it may be used again.

From the crude blue product thus obtained, which is a fluid of the consistency of treacle, all the different qualities of blues found in the market are prepared. The cheaper qualities are obtained by simply treating the crude product several times with hydrochloric acid. This removes all the free aniline, and most of the red and purple impurities. Another similar but more effective process is employed for the preparation of the better qualities, and consists in mixing the crude product with methylated spirits of wine, and pouring it into water acidulated with hydrochloric acid, and then thoroughly washing the colouring matter, which it precipitates with water. But for the purest kinds of blue there are several processes employed; these are based upon the difficult solubility of some of its compounds in alcohol. In preparing these very pure qualities of blue, instead of starting with the crude product, one of the purified blues is taken.

(To be continued.)

New Use for Oxygen.—We are informed by M. Widemann, who is connected with the works of the New York Oxygen Gas Company, that the use of oxygen in renewing and increasing the flow of oil in petroleum wells has been so successful that a regular trade has sprung up in oxygen gas for this purpose. The gas is injected into the wells through tubes, and, mingling with the hydrocarbon vapours, forms an explosive mixture, which, when ignited, completely opens seams which have become clogged, and thus renews the flow.—*Scientific American*.

A NEW MECHANICAL FINGER FOR THE MICROSCOPE.*

By J. ZENTMAYER.

At the present time, when we are informed almost daily of some new scheme of gigantic magnitude, and while nothing short of connecting two worlds or two oceans, by cable, canal, or railroad, will create even a short-lived excitement, it may hardly seem profitable to call attention to a Lilliput engineering instrument, such as the *Mechanical finger*. But, on the other hand, while some far-sighted ones already fear this cutting through Isthmuses, tunnelling mountains, and mining whole kingdoms, might, before long, dangerously displace the centre of gravity of our earth, I can, at least, promise faithfully, that even if the instrument which I am about to describe is worked to its utmost capacity it will not appreciably disturb the equilibrium of our planetary system.

In the study of diatoms it has been long desired to find a substitute for the clumsy fingers of the human hand, to do the delicate work of picking up rare and valuable diatoms detected by the microscope and to transfer them to a glass slide for preservation.

Professor H. L. Smith, well-known by microscopists as the inventor of several valuable accessories to the microscope, first presented us with a very ingenious little instrument of this kind.

Messrs. John H. B. Latrobe and George Dobbin, of Baltimore, two expert microscopists, had in use for some time one of these instruments, but found it difficult to work it; and as the instrument was exceedingly well made, this proved that its construction was too complicated to give the firmness required in picking up a shell, less than one-thousandth part of an inch in length, and of which a single ounce of ocean sand contains, sometimes, many millions. Mr. Latrobe invited me to design and construct for him an instrument for this purpose.

The instrument requires many adjustable movements, and each of these increases its liability to shake and spring. So I made it my object to utilise such movements, of a first class microscope stand as are not essential for other specific operations, as parts of the new finger. I found in the movements of a mechanical or sliding stage the main movements required in the finger, and so attached the apparatus to the mechanical stage. This gave me two of the most important movements, with a firmness and with dimensions of parts for which, otherwise, there would be no room.

This step, however, made it necessary to provide for another stage; but as there is never a higher power than a $\frac{1}{2}$ employed with such an apparatus, a plain stage with some simple arrangement to hold the slides would be found quite sufficient. Such a one was therefore arranged. The cut represents the finger attached to one of my large microscopes.

A is the top plate of the mechanical stage; the circular plate is omitted. The cap, B, is fitted to the lower body below the stage, into which cap the new substage, C, is fastened by a narrow tube, wide enough to admit illumination from the mirror. As the lower body is movable up and down by a rack, another movement is gained which is necessary to accomplish our result. The difference of the size of the aperture of the stage and the diameter of the tube, which connects the sub-stage with the cap, A, is equal to the movement of the mechanical stage, and this is found more than sufficient.

D is the clamp by which the finger is attached to the stage by means of the screw, E. A steel cylinder, G, is nicely fitted into the top and bottom of the tube, F, leaving room inside for a light spring to press the steel cylinder upwards. To prevent turning, the spring, J, is provided at H with a steel pin, accurately fitted into the fork at the top of the tube, F. By turning the

nut, K, the spring, J, is elevated and depressed, giving nice adjustment to the needle, N, in case the finger is to be attached to a microscope, not having rack-movement to the cap, B, to bring the end of the hair and the object in close approximation.

The end of the spring, J, forms a little ring, with a screw cut inside, into which a cork, M, is screwed to receive a needle, N, to which a hair is fastened by wrapping gum-paper around. Turning the cork facilitates the adjustment of the air to the proper inclination. A slight pressure on the button, L, brings down the hair, and the spring, inside of F, instantly lifts it again when the pressure is removed.

The tube, F, turns in the clamp, D, in order to adjust the hair and cork more conveniently, and when brought back again it is tightened by a set screw.

Complicated as it may appear, only one movement is added to the microscope stand by this instrument, the one, namely, which gives the vertical motion. When the apparatus is to be used, the material you want to select from is placed on the sub-stage, C, and focussed, then the point of the hair is approximately brought over

the selected object by means of the stage movements and turning of D; this brings the hair nearly in focus too, because it is almost in the same plane with the object. We next adjust the hair, recisely over the selected shell, press down the button, L, and the shell will adhere to the hair. Now we remove the slide with the material and substitute a glass slide, moistened by breathing on it, and having brought it in proper position, briskly dip down the button, L, again and the shell will be deposited on the glass slide. As the mechanical stage has a graduated indicator, the finger may be moved along regularly, and shells may be placed at equal distances in lines. After the cover-glass is carefully placed over it, then Canada balsam may be run in by capillary attraction without disturbing the position of the shells.

Philadelphia, April, 1870.

NOTICES OF BOOKS.

Report on the Quality of the Milk Supply of the Metropolitan District (New York). By C. F. CHANDLER, Ph.D., &c. New York: D. Appleton and Co. 1870.

The paper before us, an extract from the Fourth Annual Report of the Metropolitan (New York) Board of Health, opens with a statement which proves that (in matters of what is very tersely, yet aptly, called *administration de la sureté et salubrité publique*) the City of New York is not only not behind, but greatly in advance of a great number of European cities and towns, where investigations as regards milk supply are, as yet, *in nubibus*. Dr. Chandler's Report opens with the quotation of two analyses of pure milk—viz., one by Dr. Letheby and one by Harden. The general and well-known properties of milk are next

* Communicated by Professor Morton. From advance-sheets of the *Journal of the Franklin Institute*.

briefly alluded to, and attention called to the fact that the composition of milk is affected by a variety of circumstances, among which may be mentioned the breed of the cow, her age, the age of her calf, nature of food, and time and frequency of milking. These particulars are illustrated by quotations of various analyses, made at various epochs, by MM. Vernois, Becquerel, Chevalier, and A. Müller, put down in tabulated forms. We next find the description of the methods of analysis, as follows:—

"1. The water is determined by evaporating a weighed quantity of milk, either alone, or soaked up in a known weight of pure, fine quartz sand. The residue is carefully dried at 212° F., and weighed. The loss in weight represents the water, while the residue includes all the solid constituents.

"2. The salts are determined by carefully burning off the combustible portion of the solid residue obtained by evaporation, and weighing the incombustible ash.

"3. The butter and caseine are determined by coagulating the milk with a few drops of acetic acid, boiling, washing the precipitate with water, and finally separating the butter with ether, leaving the caseine pure. On evaporating the ether, the butter is left behind, or the butter may be extracted by ether from the residue obtained by the evaporation of a quantity of milk, soaked up in sand.

"4. The sugar is generally determined by deducting the sum of the other constituents from 100. It may be directly determined by the polariscope, after the removal of the caseine and butter, or it may be determined by an alkaline solution of copper."

The adulteration of milk is briefly, but ably, summarised in the following terms:—

"Numerous substances are mentioned as having been used, or as supposed to be used, for adulterating milk. Prominent among these are—

"1. *Water*.—Adulteration of this substance is generally detected by the sp. gr. of the milk. Pure milk varies in sp. gr. from 1.023 to 1.034, water being represented by 1.000. Milk is heavier than water, on account of the caseine, sugar, and salts, which it holds in solution. Butter, on the other hand, is lighter than water, therefore the sp. gr. of milk increases with the percentage of caseine, sugar, and salts, while it diminishes with the percentages of water or butter. It is found that good milk generally has a sp. gr. of from 1.029 to 1.032. In testing milk, the lower number is selected as a fair gravity for pure milk; and whenever the gravity falls below this number the milk may be considered as containing an excess of water, and consequently poor in quality or adulterated. An instrument, called a galactometer, has been devised by Dinocourt, for the purpose of testing the quality of milk. It is simply an areometer, so graduated that 100 on the scale represents pure milk, or the gravity 1.029, while 0 represents pure water, or gravity 1.000, the space between being divided into 100 parts. The numbers on the scale represent, therefore, the percentages of pure milk.

"Skimmed milk, having been deprived of most of its butter, is heavier than whole milk. By skimming the milk before testing it with the galactometer, the error caused by the butter is eliminated. In this case, however, the mark for 100, or pure milk, must be placed lower down on the instrument, as pure milk, having a sp. gr. of 1.029, would, after being skimmed, have a gravity of about 1.033. The 100° mark for skimmed milk is, therefore, fixed at this point.

"The *lactometer* is a simple tube closed at the lower end and graduated in hundredths. It is designed to measure the quantity of cream which rises on the milk.

"By using the two instruments together, the *galactometer* and the *lactometer*, very satisfactory conclusions, with regard to the quality of the milk, can be formed. A perfectly reliable method, though more laborious, is to actually determine the percentage of water in the milk, by evaporating a weighed quantity, and carefully drying the residue at 212° F. If a milk loses more than 88 per cent

of water, having less than 12 per cent of solids, it may be safely pronounced to be adulterated with water.

"2. *Chalk*.—This substance is generally supposed to be extensively used to neutralise the acidity in soured milk, and to produce thickness and opacity, thus concealing dilution with water. It is easily detected, as it is deposited on standing, and can then be recognised by its effervescing with dilute acids. I have never detected it in any sample of milk examined. In presence would also be shown in a milk analysis, by the unusual amount of ash.

"3. *Flour, starch, emulsions of almonds, or hemp-seed, &c.*, are said to be used to thicken milk and neutralise the blue colour caused by dilution. They were not found in any of our samples.

"4. *Sugar, gum, dextrin, and borax*, to increase specific gravity.

"5. *Turmeric and annatto*, to hide the blue colour.

"6. *Cerebral matter, sheep's brains*, to thicken watered milk, easily detected by the microscope, and by its depositing a peculiar white sediment on standing.

"7. *Carbonate or bicarbonate of soda*, to neutralise acidity. Detected by the increase in the quantity of ash, or, better, by the effervescence of the ash with acids."

The author next relates his researches on the milk as supplied to the inhabitants of New York. Four distinct series of analysis were made, the second series embracing 210 samples, the following determinations being made in each case:—(1) The specific gravity; (2) the percentage of pure milk, as shown by the galactometer; (3) the percentage of water; (4) the percentage of solid matter, including butter, caseine, sugar of milk, saline constituents, &c.; examination for adulterations. The results are printed in tabular form, and prove the following facts:—The sp. gr. varies from 1.010 to 1.032, averaging 1.0208; the percentage of pure milk, as shown by the galactometer, ranges from 37 to 110, averaging 72½; the percentage of water varies from 83.57 to 94.17, averaging 89.89; the percentage of solid constituents, the nutritive portion of the milk, varies from 5.83 to 16.43 per cent, averaging 10.11. No adulteration, save water, was found in a single instance.

The general conclusion arrived at by the author establishes the fact that the citizens of New York and neighbourhood receive milk free from injurious adulterations and untainted with disease, but adulterated with water to the extent that for every three quarts of pure milk there is added one quart of water. The quantity of water thus paid for as milk, at ten cents per quart, costs about 12,000 dollars a day, or 4,000,000 dollars annually. Our readers will agree with us that the ably-written paper, from which we have largely quoted, treats on a subject of great interest, not only to New York, but to the inhabitants of all large cities and towns, where the good example of the New York authorities may be advantageously followed.

Reports on the Water Supply of New York and Brooklyn.

Chemical Report by C. F. CHANDLER, Ph.D., &c.

Microscopical Report by WILLIAM B. LEWIS, M.D.

New York: D. Appleton and Co. 1870.

THIS paper contains, in its first part, chiefly the tabulated results of the researches and analysis, made by Dr. Chandler, of the Croton and Ridgewood waters, as supplied to the cities above named, during a portion of last year. It appears that the Croton water contains, in 1 United States' gallon (231 cubic inches), 4.78 grains of total solid matter, while the oxygen required to oxidise the organic matter amounted to 0.0618 grains. The paper contains, also, in tabulated form, a review, showing the purity of the Croton and Ridgewood water, as compared with the waters of other American as well as European cities. Special attention is called to the presence of lead in the Croton water, derived from the leaden service-pipes and lead-lined cisterns it passes through or is kept in. A gallon

(United States) of water which had remained for six hours in the lead pipes of Dr. Chandler's residence, yielded 0.11 grains of metallic lead, a considerable portion of which was visible to the eye, in the minute white spangles of the hydrated oxycarbonate. The author states that "tin-lined," or "lead-encased block-tin" pipes, are being gradually introduced instead of the leaden pipes. These, we may observe, can be rendered perfectly safe, if, before being put down, they are internally syringed through with a strong and hot solution of any alkaline sulphide, which will very effectually convert the metal into sulphuret of lead, which, as proved by Professor Moss Pettenkofer, is not acted upon at all, even by rain or distilled water.

The able Microscopical Report, illustrated by two lithographs, shows the necessity of very effective filtration, even of otherwise pure water.

We may congratulate the citizens of New York on the care taken for their welfare by the Board of Health, and that Board for having found men who evidently are doing their utmost to promote the good health and material well-being of their fellow citizens.

CORRESPONDENCE.

SUPPOSED FORMATION OF OZONE DURING COMBUSTION.

To the Editor of the Chemical News.

SIR,—Referring to Mr. Loew's note on "The Formation of Ozone by Rapid Combustion," inserted in a recent number of the *CHEMICAL NEWS*, vol. xxii., p. 13, allow me to mention that, in repeating Mr. Loew's experiment, with this slight modification, that a stream of oxygen instead of air was blown through the luminous flame of a Bunsen's burner into the mouth of a glass balloon, I really found that the air in the balloon had assumed a peculiar odour, and the property of colouring blue a mixture of starch paste and kalium iodide.

Both changes are the result of the formation of a compound of oxygen and nitrogen (probably dinitric trioxide or nitric dioxide), not from the formation of ozone, as Mr. Loew asserts.

The gas in the balloon being shaken with a little water, this was unable to colour the kalium iodide starch; kalium hydroxide, however, shaken with the gas, caused a dark blue colouration in the mixture, after having been acidified with dilute sulphuric acid. It is almost unnecessary to add that I had first assured myself by a blank experiment that the iodide was sufficiently free from iodate not to cause errors.

With ferrous sulphate and strong sulphuric acid it gave the characteristic reaction of nitrates and nitrites.

So when Mr. Loew declares that he was able to "identify the formation of ozone by its intense odour and the common tests," he was a little rash in this conclusion.

The odour is that of the coloured compounds of oxygen and nitrogen, the presence of which was moreover proved by the common tests.

Unhappily till now, except perhaps thalious oxide, the known tests for ozone and nitric trioxide, &c., are "common" to both.

Still Mr. Loew's experiment is a very interesting and easy one, and will soon take its due place in the series of lecture-experiments intended to elucidate the complex phenomenon of combustion.—I am, &c.,

J. D. BOEKE, Phil. Nat. Doct.,
Teacher of Chemistry at the Hoogere
Burgerschool at Alkmaar.

DETERMINATION OF FERROUS OXIDE IN SUBSTANCES INSOLUBLE IN ACIDS.

To the Editor of the Chemical News.

SIR,—I have read with great interest the method of estimating ferrous oxide in silicates described by Messrs. Wilbur and Whittlesey in the *CHEMICAL NEWS*, vol. xxii., p. 2. The method is just what was required, and will doubtless be found equally available for the analysis of such iron slags as are not completely decomposed by hydrochloric acid. The results of the analysis of Trap A. by Mr. Wilbur are not very constant, varying from 9.37 per cent to 11.95 per cent of ferrous oxide, and I am inclined to believe the fault lies in the method of titration employed.

It has been repeatedly shown that the presence of hydrochloric acid interferes appreciably with the estimation of iron by permanganate, while it does not affect Penny's bichromate process. If the former oxidising agent be employed, the solution should be effected by means of sulphuric acid.

This source of error seems to have escaped notice almost entirely, although most distinctly pointed out in "Fresenius," and also in Sutton's "Volumetric Analysis."

Apropos of the estimation of ferrous oxide in difficultly soluble compounds, I may mention that solution may frequently be effected by heating with hydrochloric acid under pressure. I have used this method very successfully in the analysis of various titaniferous iron ores and sands. About a gramme of the finely powdered mineral is heated in a sealed piece of combustion tubing, half full of fuming hydrochloric acid. At first the heat of a water-bath is sufficient, but after a few hours the temperature is gradually raised to 140° or 150° C. The ore is completely decomposed in four or five hours, and after the tube has cooled the end may be broken under water, and the ferrous oxide at once estimated by bichromate.

Of course the same method will yield a solution suitable for the determination of the other constituents of the ore.—I am, &c.,

ALFRED H. ALLEN, F.C.S.

School of Chemistry,
Sheffield, July 23rd, 1870.

COMPOSITION OF CARMINE.

To the Editor of the Chemical News.

SIR,—In your review of Mr. J. W. Slater's "Manual of Colours and Dye Wares" (*CHEMICAL NEWS*, No. 556), Mr. Slater is severely criticised for stating that carmine is the colouring matter of cochineal in a pure state combined with alumina. You say, "It is readily soluble in ammonia, and does not contain alumina at all," implying, at the same time, that this fact was brought about by recent researches.

Permit me to say that I have been for several years engaged in working out the chemistry of carmine, and perfecting the method of its preparation on a large scale, and that, according to my experiments, carmine, although easily soluble in ammonia when pure, is an alumina compound.—I am, &c.,

HUGO MÜLLER.

[In both the French and German editions of Schützenberger's work on Dye Materials, recently published, it is said that perfectly pure carmine does not contain any alumina, and, moreover, leaves no ash on its ignition. This author also states that there are different qualities of carmine met with in commerce, and that only the more ordinary qualities contain alumina. A similar statement to the above is also contained in the "Handwörterbuch der Reinen und Angewandten Chemie, Art.

Carmin," written by J. von Liebig, and in Persoz's standard work, "De L'Impression des Tissus." The reviewer may also refer those who are interested in the subject to the mode of preparing carmine of Madame Cenette, in which (as may be learned from the detailed description of this process, in Ure's "Dictionary of Arts, &c.," 6th edition, vol. i., p. 654; and also Cooley's "Cyclopædia of Practical Receipts," 4th edition, p. 399) no alum whatever is used; whilst the result is the production of the finest carmine of great purity. In the book reviewed, the author has not made any distinction between the different qualities of carmine and carmine lake, and speaks about carmine as if it were a well-known chemical compound of alumina, which it certainly is not. Of course, when so eminent a chemist as Dr. Müller says that alumina is an essential constituent of pure carmine, we accept the statement as correct; but, as it is a fact which was unknown to Schützenberger, Persoz, Ure, Von Liebig, as well as to Madame Cenette, a most successful manufacturer, the reviewer may, perhaps, be excused for not being acquainted with it.—THE REVIEWER.]

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, July 18, 1870.

This number contains the following original memoirs and papers relating to chemistry and collateral sciences:—

Magnetic Rotatory Power of Liquids.—A. de la Rive.—The author, in a letter to M. Dumas, states that he has just finished a series of experiments on the above-named subject, the results of which will be shortly published. The first portion of this work is devoted to the description of the apparatus and processes of experimentation; the second part contains the results of the determination of the magnetic rotatory power of some liquids. As a curious anomaly, the author mentions that, taking water as unit, the coefficient of the magnetic rotatory power of monohydrated sulphuric acid, (HOSO_3), is 0.750, and that coefficient is, for liquid anhydrous sulphuric acid, (SO_3), equal to 1.240 at a temperature of 12°. The third part of this work is devoted to the study of the influence of the temperature on the magnetic rotatory power. In the fourth part, the author gives the results of his investigations of the magnetic rotatory power of a mixture of two liquids, as compared with that each of these liquids possesses separately. The fifth part contains the results obtained by experimenting with two isomeric liquids.

New Researches on the Electro-Capillary Action: Formation of Crystallised Oxychloride of Copper and other Analogous Compounds.—M. Becquerel.—This paper contains another instalment of the author's researches, which have occupied his attention for a series of years. The artificial formation of the oxychloride of copper in crystalline state, and exactly similar to that found in the copper mines of Peru and Chili, and known as atacamite, has taken no less than fifteen years.

Observations of the Underground Temperature in the Jardin des Plantes, at Paris, from 1864 to 1870.—A. C. Becquerel and E. Becquerel.—From this lengthy paper, we learn that, at 36 metres below the surface, the temperature is constantly 12.47°, and that at a depth of from 36 to 26 metres a very slight difference only is observed. The paper contains a lengthy series of tabulated results.

Variations of Temperature produced by the Mixing of Two Liquids.—H. Sainte-Claire Deville.—A sharp reply to the last communication on this subject by M. Jamin.

Reply to the Criticism of M. Jamin in reference to a paper published in 1860.—H. Sainte-Claire Deville.

Researches on the Action of the Chlorides of Platinum, Palladium, and Gold upon Phosphines and Arsines.—A. Cahours and H. Gal.—This lengthy memoir is divided into the following sections:—Action of bichloride of platinum upon arsines; action of chloride of palladium upon triethyl-arsine; action of sesquichloride of gold upon triethyl-arsine.

Thermal Researches on the Metallic Character of the Alloy of Palladium with Hydrogenium, and on a Voltaic Element wherein Hydrogenium is the Active Metal.—P. A. Favre.

Possibility of Obtaining Luminous Signals Visible at Great Distances.—F. Lucas.

Photographical Studies of the Sun at the Imperial Observatory at Paris.—L. Sonnel.

Decomposition of Oxalic Acid.—P. Carles.—The author describes at length, a series of experiments, the chief result of which is that a current of even an inert gas (as, for instance, hydrogen or nitrogen) decomposes, or, rather, dissociates, at 100°, a concentrated aqueous solution of oxalic acid.

Conversion of Chloral into Aldehyde by Inverse Substitution.—J. Personne.

Crystalline Compounds of Oxide of Lead and Oxide of Antimony, and of Oxide of Lead and Antimonic Acid, from the Province of Constantine (Algeria).—M. Flajolot.—The minerals just mentioned are—A compound of oxide of antimony and lead, $\text{Sb}_2\text{O}_3 \cdot 2\text{PbO}$; sp. gr., 7.02; colour, smoky brown; hardness, that of carbonate of lime; soluble even in dilute hydrochloric acid, if applied in large bulk, and also in a mixture of dilute nitric and tartaric acids. The other mineral consists, in 100 parts, of—Oxide of antimony, 4.80; antimonic acid, 35.50; carbonic acid, 4.20; oxide of lead, 51.50; water, 4.0. Formula, $\text{Sb}_2\text{O}_3 \cdot \text{PbO} + \text{CO}_2 \cdot \text{PbO} + 2\text{H}_2\text{O}$. Besides these crystalline compounds, the same mineral vein, chiefly containing calamine stone, contains an amorphous ochry substance, consisting, in 100 parts, of—Antimonic acid, 63.50; sesquioxide of iron, 31.40; water, 5.10. Formula—

These minerals occur at a distance of 60 kilometres to the south of Bône, near to a thermal spring much frequented by the Arabs, and known as Hamman-Nbaïl-Nador.

Programm der Königlichen Rheinisch-Westphälischen Polytechnischen Schule zu Aachen, für den Cursus, 1870-71.

Under the above title, the director of this school (which was briefly alluded to at page 23 of our present volume), has kindly forwarded to us this volume, containing, beside some sixty pages letter-press, several tabulated forms (of which more presently); also a series of engravings representing the plans and outline of the building. From this work we abstract the following:—On November 14th, 1863, His Majesty the King of Prussia decreed that Aachen City (Aix-la-Chapelle, Charlemagne's imperial residence) should be the seat of the High Polytechnic School to be established for the Rhenish provinces and Westphalia, and on the 15th of May, 1865, the anniversary of the fiftieth year of the annexation of the Rhenish provinces to Prussia, His Majesty laid the foundation stone of the building, in the portico of which are placed the marble busts of the King and the Prince Royal. The walls of the building are made, in the first place, as far as the foundation and basement are concerned, of trachyte from the Drachenfels, near Bonn; next follows red sandstone, from the neighbourhood of Trèves; while the higher stories are executed in tuffstein, from Brohl (a kind of volcanic stone). The façade of the main building is in the early Italian renaissance style, bearing the coats of arms of the city of Aix-la-Chapelle, of Rhenish Prussia, of Westphalia, and the allegorical representations of science as Minerva with the Prussian eagle and of Borussia. The building is constructed to accommodate, with ease, 500 students, and covers a surface of 28,577 square feet. The so-called aula (a large lecture-room) is ornamented with medallions bearing bas-relief busts of the following celebrated men, the names of some of whom may, however, not be well-known to our readers:—Von Dechen, Beuth, Werner, Von Liebig, Bunsen, Magnus, Dove, Karmarsch, Bessel, Schinkel, Mellin, Von Buch, Von Humboldt, Klaproth, Mitscherlich, Liebnitz, Gauss, Redtenbacher, Borsig, and Hagen. The building is heated by hot water, and contains four tanks, each of 1000 cubic feet capacity, which are filled by means of steam pumps. Water is laid on throughout the building so as to be accessible for use in every part thereof, and also to serve in case of fire. A very good clock, with large dial-plate, and striking the hours and half-hours, is placed in the portico of the building, and, by means of electricity, the laboratory clock-dial is in connection with that of the main building. The chemical laboratory is not situated in the building just alluded to, but is a building by itself, standing in the garden and behind the main school-building. This laboratory building consists of basement and two stories (it covers 7912 square feet), and is divided into two main sections, one of which is devoted to pure, the other to technical or applied chemistry. Each of these sections contains complete laboratories, fitted up with all modern requirements, and arranged so as to accommodate, beside, sixty students for practical chemistry classes and the investigations for more advanced students. The staff attached to this establishment consists of a director; 3 heads of special schools (viz., for engineering and architecture, engine construction and mechanical technology, and chemical technology and metallurgy); 17 ordinary professors; 7 extraordinary professors; 7 assistants; 4 private teachers; a general secretary and treasurer; a librarian and scientific correspondent; and, further, 1 housekeeper (*castellan*) for the main building, 1 ditto for the laboratory, 3 porters for the laboratory, 1 machinist and foreman of the workshop, 2 stokers, and a general male servant. It is quite impossible to enter into details about the lectures, or to give any adequate description of the amount even of the material means provided to aid the instruction in this noble institution. The expenses of first establishment are £80,310, and of this £7800 has been spent upon the chemical and chemical-technical portion and laboratories, over and above the expense incurred by the separate building. None

of the students will reside in the building, which is not a college, in the sense that word is usually applied; and, in order to make clear for them the courses of lectures they will have to attend, tabulated forms have been added to this volume, one of which is very ingeniously contrived, being partly printed in colours and letterpress text, and the whole so arranged that the white spaces indicate the courses to be attended to by the students of the first year, yellow second year, green third year; the fourth year for architects and engineers is red, and for mechanic-technics blue. The lectures commence at 8 a.m., and, with the exception of 1 hour's rest, continue till 6 p.m. We may not neglect to observe that the Prussian Government has provided liberally for the proper maintenance of this school, which has been planned with the view of rendering the instruction to be given readily accessible to all. The Aix-la-Chapelle and Munich Fire Insurance Company has liberally made a grant of a capital of £3000 to the school, the interest of which is to be applied to assist some few students to pursue their studies, under certain regulations. The School is to be opened on October 10th next.

Revue des Cours Scientifiques de la France et de l'Etranger,
July 16, 1870.

This number does not contain any original papers on chemistry or collateral sciences, but we notice briefly—

Manufacture of Glass.—M. Bontemps.—Under the title of "Guide du Verrier, Traité Historique et Pratique de la Fabrication de Verres, Cristaux, Vitraux" (that is to say, The Glassmaker's Guide, Historical and Practical Treatise on the Manufacture of Glass, Crystal, and Sheet Glass), the author has published a large amount of information, valuable not simply for France, but also for other countries. The extent of the glass manufacture in the country just named may be inferred from the following few scraps:—The total annual production of all kinds of glass, bottles inclusive, is 177,300,000 kilos.; the weight of the raw material for this production amounts to 220,260,000 kilos.; weight of fuel required, 557,500,000 kilos.; number of workmen engaged in this branch of industry, 20,000.

Cosmos, July 16, 1870.

Utilisation of the Waste Heat of Gas-Work Furnaces.—V. Meunier.—The author proposes that the waste heat shall be applied to the heating of the air which is required to keep up the combustion of the fuel intended to keep the retorts at the requisite degree of heat. This proposal may be executed in practice in various ways, but it appears that the best plan is the construction of brick chambers, wherein the products of the combustion are made to pass in a zigzag manner previous to entering the chimney-stalk, and to heat the air contained in tubes.

Painting by means of Injection.—M. Violette.—The author employs a so-called pulveriserator (spray-producing machine) for the application of pigments and dyes to the surface of textile fabrics, paper, &c. The coloured liquid is projected in an impalpable spray, and made to fall on the objects to be painted or dyed, as the case may be.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 10,
1870.

This number contains the following original papers and memoirs:—

On Phthalyl.—E. Ador.—The author, in the first place, describes at length his experiments on the elimination of chlorine from organic combinations, by means of finely divided silver; by this means the chloride of phthalic acid has been decomposed, and phthalyl obtained as a solid substance, insoluble in water, very difficultly soluble in alcohol, ether, chloroform, and sulphide of carbon, not attacked by bromine and sulphuric acid, and sublimable at a high temperature; boiling nitric acid oxidises phthalyl, yielding phthalic and diphtalyl acid. The formula of phthalyl is—

The author in this lengthy memoir enters into full details on the constitution of phthalyl and compounds derived therefrom.

Reduction of Isatine to Indigo Blue.—A. Baeyer and A. Emmerling.—The authors state that when isatine, previously pulverised, is mixed with fifty times its weight of a mixture of equal parts of terchloride of phosphorus and chloride of acetyl, to which some phosphorus is added, and this mixture is heated for several hours to from 75° to 80° in a sealed tube, and the bright green coloured liquid contained in the tube poured into a large bulk of water, next filtered, and substance is gradually deposited, which, being collected on a filter and washed with alcohol, yields a body in all its properties fully identical with indigo blue. The quantity so obtained varies from 10 to 20 per cent. of the weight of the isatin employed. The authors enter at great length into collateral matters of interest as regards the synthesis of indigo blue; but unless we were to produce a series of complicate formulae, we could not give any useful abstract of that portion of their paper.

Action of Solid Chloride of Cyanogen upon Benzyl Alcohol.—S. Canizzaro.—By the action of the solid chloride of cyanogen, C_3Cl_3 , upon benzyl alcohol, the author has obtained three different substances, viz., a small quantity of a solid body crystallising in the shape of small needles, fusing at 153°, and which may be a cyanide of

benzyl, but owing to the very small quantity obtained of this substance, the author could not say for certain; next another solid body, crystallising in large prismatic shaped crystals, and containing, in 100 parts—Carbon, 75.31; hydrogen, 6.15; nitrogen, 11.10; lastly, another solid body, fusing at 86°, and found to be benzyl urethan—

Synthesis of the Oil of Rue.—Gorup-Besanez and F. Grimm.—After referring at length to the researches made by a great number of authors for the purpose of the artificial production of the oil of rue (*Ruta graveolens*), the authors state that they succeeded in obtaining this product synthetically, by the dry distillation of equal molecules of capric and acetate of lime. This is the chief point of interest in this lengthy memoir, which contains a lengthy description of the experiments and discussion on the rationale of the reactions.

Contribution to our Knowledge of Meteorites.—C. Rammelsberg.—The author describes a series of minerals, and states that, in his opinion, the true nature of meteorites can only be learned by paying attention to the composition of the minerals constituting those bodies.

Non-existence of the Chlorocyanide of Hydrogen.—A. Naumann and E. Vogt.—The authors state that while experimenting upon the dissociation of gases and vapours, they have found that the chemical compound $2\text{C}_2\text{Cl}_2\text{C}_2\text{H}_2$ does not exist as such, but is simply a mechanical mixture of chloride of cyanogen and hydrocyanic acid.

Action of Bromine upon Dichlorhydrine.—A. Claus.—A reply and critical review of Dr. Carius's papers on this subject, published in No. 8 of this periodical.

Action of Chloride of Sulphur upon Aniline.—A. Claus.—Only a preliminary communication.

Researches on the Ether Derivatives of the Polyatomic Alcohols and Acids.—L. Henry.—Fourth paper on this subject, containing the following sections:—On different nitric ethers, nitric ether of the ethylglycol, nitric ether of the alcohol acids.

Elementary Bodies.—C. W. Blomstrand.

Constitution of the Combinations of the Camphor Group.—H. Hlasiwetz.—Chiefly a series of very lengthy and complicated formulae.

Contribution to our Knowledge of the Anthracen Pigments, and on the Preparation of Anthracen in Pure State.—V. Wartha.—This paper is too lengthy and too concisely written to admit of any useful abstraction.

On Azotoluol and some of the Derivatives thereof.—This memoir is divided into the following chapters:—azotoluol, azoxyloluol, hydrazotoluol, tolidin.

Basicity (Basicität) of Acids.—F. Mohr.—An exhaustive and lengthy essay.

Occurrence and Elementary Composition of Vegetable Wax.—J. König.—This memoir contains chiefly the results (in figures) of a series of experiments made with a variety of fresh and dried vegetable matters, hay, straw of various kinds of corn, &c.; also researches on the wax contained in the excrements of cattle, horses, and sheep fed with these vegetable products.

The Association for Mineral Oils at Halle on the Saale.—This body corporate desires to obtain: 1. The best information concerning the chemical means of purifying crude paraffin cakes, so that the loss of paraffin does not thereby rise above 5 per cent. 2. A contrivance whereby materials containing paraffin may be cooled down at any season of the year to at least -5°C . In reference to No. 1, among other conditions are—that are excluded from use such substances as colourless tar oils, benzine, and, generally speaking, any substances which either dissolve or alter paraffin, the operation, moreover, ought to be readily executed and suitable for working on the large scale; the paraffin should be free from smell, and be of a bluish white colour. In reference to No. 2, the contrivance ought to be such as to enable to cool down daily at least 500 cwt. in quantities of 5 cwt. at a time. The association is inclined to give two premiums, each at £750 value, for the best of the contrivances asked for, the time being fixed for the 1st of January, 1871. Apply to the Mineralöl-Verein zu Halle a. d. S. Prussia. The committee of examination consists of several parties, among whom M. A. Riebeck at Halle.

Les Mondes, July 7, 1870.

Universal Origin of the Prototype of the Measures of Length.—Dr. Rodenbach.—The author says the elbow-length of a well-developed man is the third part of the mean height of men all over the world, and that length, equal to 0.54 metre (taken three times, equal to 1.62 metres, the average height of men on the globe), has served to derive therefrom all linear measures, and from these have been derived the surface (square) and cubical measures, as well as weights, and, in later times, has become (with Assyrians, Chaldeans, and Egyptians) the basis, also, of the monetary system.

Movable Rotating Gas-Burner Producing a Helicoidal Flame.—M. C. Woestyne.—This burner, according to what is here stated, consumes gas very completely, so that no smoke or soot is ever produced, and the activity of the combustion (fed by 60 cubic metres of air = 1019.2 cubic feet per hour) both renders the light brilliant, and is a great auxiliary to ventilation.

Inclination of the Axis of the Basilica of St. Peter, at Rome.—Rev. Father Angelo Secchi, S.J.—This eminent savant writes to the Editor of *Les Mondes* on this subject, explaining the cause of what now

is clearly made out to have been an optical illusion (alluded to in the *CHEMICAL NEWS*, vol. xvi., p. 24), traced by the writer of this note to its due cause, who, however, does not fail to point out some irregularities and eccentricities in the building alluded to, but which, as a consequence of its enormous size, are not perceptible, unless by very careful survey. The author's object in writing on this (at Rome) well-known subject is to prevent the rumour getting abroad of defects existing which impair the stability of the Basilica, which, having been thoroughly surveyed, is found as firm as a rock. M. Narucci writes also on this subject, and both letters will greatly interest builders and architects especially.

Explosion of Picric Acid Induced by Ozone.—Rev. F. Moigno. When picric acid is introduced into a vessel containing ozone, a violent detonation instantaneously takes place, a new proof of the danger attending experiments with nitrogenous compounds containing nitrogen only loosely bound.

Curvigraph.—M. Bellanger.—A description, accompanied by woodcuts, of a very useful instrument, intended to draw upon paper all curved lines and curvilinear figures of which a certain number of points are known.

Centrifugal Mixer.—C. Woestyn.—A lengthy description of a contrivance, especially suited to operations in sugar refineries, to separate, from viscous fluids, solid and liquid matters.

Aspirating Ventilator.—Damboise-Bénard.—With woodcuts. A very ingenious contrivance for getting rid of foul air, as well as sucking fresh air in simultaneously.

Continuous Syphon, and Substitution of Syphons for Pumps in Drainage Works, &c.—M. de Lagillardais.—With woodcuts. Useful and ingeniously-made apparatus.

July 14, 1870.

Inauguration of the Kepler Monument.—On the 24th of last June, the very small Swabian town named Weildstadt, with hardly 2000 inhabitants, was the scene of a festive gathering for the purpose of unveiling the statue of the celebrated Kepler, who was born in an humble cottage yet existing, and now known as Keplerhaus. The statue of the celebrated astronomer, executed in bronze, represents him seated on an arm-chair, in his left hand, supported by a celestial globe, he holds a scroll, upon which an ellipse is delineated; in his right hand he holds a pair of opened compasses. At the four corners of the pedestal, upon which the statue is placed, are smaller statues, representing Michel Mastin, the Tübingen professor who taught Kepler mathematics, and Nicholas Copernicus, Tycho-Brahé, and John Beyer, who assisted Kepler in making astronomical instruments. On the centre of the pedestal is simply placed "Kepler"; the other sides of this portion of the monument are embellished with bas-relief representations of incidents of Kepler's life.

Journal für Praktische Chemie, No. 10, 1870.

This number contains the following original memoirs and papers:—**The Polybromides of the Tetra-Ammonium Bases.**—P. C. Marquart.—Conclusion of this memoir, to which Prof. Kolbe has added a short paper on the—

Highest Capacity of Saturation (Valenz) of the Elementary Substances.

Composition of Lawrowite and Vanadiolite, a New Mineral.—R. Hermann.—After referring at some length to the history of the two minerals above-mentioned, the author says:—Lawrowite, named after a Russian mineralogist, is a substance of 3.04 sp. gr., exhibiting a grass-green colour and glassy lustre. Heated before the blowpipe-flame it fuses to a bright green-coloured glassy mass, does not lose any weight by ignition, and contains, in 100 parts:—Silica, 53.65; alumina, 2.25; protoxide of iron, 24.8; lime, 23.05; magnesia, 16.0; hypovanadic acid ($\text{VO}_2 + 2\text{VO}_3$) (intervanadous), 2.57. Vanadiolite, sp. gr. 3.56, fuses before the blowpipe-flame at the edges, forming a black slag. It is a crystalline, nearly black-coloured, body, consisting, in 100 parts, of:—Silica, 15.61; alumina, 1.10; protoxide of iron, 1.4; lime, 34.43; magnesia, 2.61; hypovanadic acid, 41.85; formula— $3\text{ROSiO}_4 + \text{CaO} \cdot (\text{VO}_2 + 2\text{VO}_3)$.

Probable Identity of Laxmannite and Vauquelinite, and on Phosphorchromite, a New Mineral.—R. Hermann.—The first part of this memoir contains a discussion, illustrated with the results of a series of analyses made by the late Berzelius and Dr. Nordenskjöld, and here mutually compared to prove that laxmannite and vauquelinite are identically the same, both as regards their chemical composition as also their mineralogical features. As regards the phosphorchromite, this mineral has been, the author says, also confused with vauquelinite, but, since the author's analysis has proved that this mineral contains far more oxide of lead than vauquelinite, he has termed it phosphorchromite, consisting, in 100 parts, of:—Oxide of lead, 68.33; oxide of copper, 7.36; protoxide of iron, 2.80; chromic acid, 10.13; phosphoric acid, 9.94; water, 1.16; formula, $3\text{CuO} \cdot \text{P}_2\text{O}_5 + 5\text{PbO} \cdot \text{CrO}_3 + 3\text{H}_2\text{O}$.

On Diphenyl.—F. Plankuch.—Preliminary notice. When phenol-potassium and benzoate of potassa are heated together, benzol and notable quantities of diphenyl are obtained, which, after having been washed with caustic soda, and distilled along with aqueous vapour, may be crystallised from boiling alcohol, and thus obtained in pure state. The author continues his researches on this subject.

Formation of Crystals in the Beads of Borax and Phosphor-Salt when Formed before the Blowpipe-Flame.—G. Wunder.—A lengthy memoir on this subject, illustrated by several lithographic plates.

Archives des Sciences Physiques et Naturelles et Revue Suisse, No. 150, June 15, 1870.

This number does not contain any original papers relating to chemistry, but the following original papers, of which we quote the titles.

The Grotto of Scé, near Villeneuve (Switzerland).—H. de Saussure.—A contribution to the history of primitive man.

Note on the Meteorological Observations made on the Coast of Labrador by Moravian Missionaries.—Dr. Gautier.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, April, 1870.

This number contains the following original memoirs relating to physical and chemical sciences:—

The Place Thallium should Occupy in the Series of the Elementary Bodies.—Dr. C. Kammelsberg.—This paper has also been published in the *Berichte der Deutschen Chemischen Gesellschaft zu Berlin*, from which we have before noticed it.

Relation Existing between Crystalline Form and the Chemical Constitution of Organic Compounds.—Dr. P. Groth.—A very exhaustive and lengthy memoir, full of formulae, but not suited for any useful abstraction.

Moniteur Scientifique, No. 326, July 15, 1870.

The only original paper relating to chemistry and its applications is a lengthy report on—

Vinage.—MM. Béclard, Bergeron, Bouchardat, Gubler, and Wurtz.—By *vinage*, a word which does not admit of being translated by a single word, is understood an operation whereby, either by the addition of alcohol, or also, of a naturally more strongly alcoholic and deeper coloured wine, some less alcoholic and otherwise less good wines are improved, or, at least, made fit to keep and rendered drinkable. This lengthy report, wherein this subject is fully discussed, winds up with a series of conclusions and propositions for the interference of the authority of Government in a matter which is not only of high importance to wine-growing, but also to all wine-consuming countries. It appears, however, that the root of the evil is partly bad cultivation of the grapes, and partly, also, a perverted taste of the public everywhere as regards the *vin naturel*—that is to say, the properly-fermented grape-juice. The authors disapprove of the addition of alcohol, even in the shape of brandy, and especially such spirits of inferior description and quality as are often used for the purposes above alluded to.

NOTES AND QUERIES.

Analysis of Alloys.—"T. W." should not have neglected to use a magnet, to separate, by its aid, previous to beginning analytical operation, any steel particles. Instead of using a file, it is better, also, if practicable, to cut, by means of a well-tempered cold chisel, the alloy intended for analysis; and the pieces cut off may, for security's sake, to prevent adhesion of iron or steel, be well rubbed over a hard stone, or with emery paper, and next cleaned with a stiff brush.

Inflammable Liquids.—(Reply to "G. G. M.")—Professor Nickles calls attention to the fact, that when the chloride of sulphur of commerce is mixed with sulphide of carbon wherein phosphorus has been previously dissolved, a fluid is formed, which, though emitting fumes when in contact with air, is harmless, and may be for any length of time kept in well-stoppered bottles; on addition of liquid ammonia, however, or on passing into this liquid a few bubbles of ammonia gas, a most intense combustion at once ensues. This is due to the fact that the ammonia seizes upon the chloride of sulphur, forming chloride of ammonium, whereby so much heat is set free as to cause the combustion of the sulphide of carbon and phosphorus dissolved in it.

TO CORRESPONDENTS.

* * Vol. XXI. of THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 11s. 10d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by their sets of volumes, are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxii. commenced on July 1st, and will be complete in twenty-six numbers.

P. H. M.—The reaction has, we believe, been observed before. You should have an experiment tried on a large scale.

T. Charters White. We are obliged for the report. Shall be glad to have further accounts of the transactions of the club.

J. Banister.—We will endeavour to give as much information on the subject as our space will allow. Single numbers of the *Bayerisches Industrie und Gewerbe Blatt* cannot be purchased in England.

Henry Watts, B.A., F.R.S.—Our publisher will send you another number.

R. Mallet, F.R.S.—We will reply by letter.

THE CHEMICAL NEWS.

VOL. XXII. No. 558.

ON THE ADULTERATION OF MILK.

By Dr. A. E. DAVIES, F.C.S., F.L.S.

THE extracts from Dr. Chandler's report on the New York milk in the last number of the CHEMICAL NEWS (vol. xxii., p. 55) raise several points of interest bearing upon the adulteration of milk. As I have devoted considerable attention to this subject, and am at present engaged on an investigation into the quality of the milk supplied in Manchester, I may perhaps be permitted to state very shortly some of my experimental results and the conclusion I have drawn from them.

As to water being the only substance which is employed for adulterating milk I perfectly agree with Dr. Chandler. Carbonate of soda and nitrate of potash are occasionally added, but only rarely, and in very small quantity. I have never met with chalk, sheep's brains, mucilage, sugar, &c., in any sample which I have analysed.

Since water, then, appears to be practically the only substance fraudulently added to milk, it is a matter of the greatest importance that we should be able to detect the presence of added water, and to estimate, at least approximately, its amount. This (at least the presence of added water) Dr. Chandler considers may be done by taking the specific gravity of the milk and by estimating the water it contains by evaporating a weighed sample to dryness. "Pure milk," he says, "varies in specific gravity from 1.023 to 1.032, water being represented by 1.000." And, again, "It is found that good milk generally has a specific gravity of from 1.029 to 1.032. In testing milk, the lower number is selected as a fair gravity for pure milk; and whenever the gravity falls much below this the milk may be considered as containing an excess of water, and consequently poor in quality or adulterated."

Now, according to my experiments, the specific gravity cannot be at all relied on as a test either of freedom from adulteration or of natural richness. I give a single example. A sample of milk of known genuineness recently analysed by me gave the following results:—Casein, 4.26; fat, 6.26; sugar, 5.13; salts, 0.60; water, 83.75; cream (by the lactometer), 17 per cent; specific gravity, 1.0246. It was, therefore, a very excellent sample, and rich in all the solid constituents of milk, especially butter, but had it been judged by its specific gravity, it would have been put down as of very inferior quality. Besides, even supposing the specific gravity to be a reliable test of quality, it gives us no indication as to whether the milk is naturally poor or has been rendered so by the addition of water, and the test, in my opinion, is therefore worthless.

As to the estimation of the amount of water by evaporation, Dr. Chandler says—"A perfectly reliable method, though more laborious, is to actually determine the percentage of water in the milk, by evaporating a weighed quantity and carefully drying the residue at 212° F. If a milk loses more than 88 per cent of water, leaving less than 12 per cent of solids, it may safely be pronounced to be adulterated."

From this view, I totally dissent; the presence of 88 per cent of water is an indication of inferior quality, but is certainly no indication whatever that water has been purposely added. In milk of known purity, examined by Dr. Voelcker, as much as 90.70 per cent of water was found; and this alone shows the untrustworthiness of Dr. Chandler's test—at least, as far as it refers to added water.

It appears to me, that what is wanted is, not a test which will simply tell us whether or not the milk contains

more than the normal quantity of water, without giving any indication whether the water has or has not been added to the milk. If this were all, the estimation of the water, by evaporation, would accomplish it; but, what really is required, is a test which will show if the milk has been purposely diluted with water, and, if so, what quantity of water has been added. Such a test, I believe, we have in the specific gravity of the serum, or liquid portion of the milk, from which the caseine and fat have been removed by coagulating and straining. The gravity of this liquid I have found to be remarkably constant, ranging, in that obtained from genuine milk, from 1.026 to 1.028; and, by carefully ascertaining the specific gravity of the serum of genuine milk diluted with various quantities of water, we may obtain a standard of comparison which will enable us to say, within a few per cents, what quantity of water has been added to any sample of milk that may come under our notice.

ON THE PRODUCTION OF CERTAIN CRYSTALLINE PHOSPHATES AND ARSENIATES.

By W. SKEY,

Analyst to the Geological Survey of New Zealand.

A GREAT many minerals occur in a natural state, which, in their chemical constitution, their crystalline form, or both combined, have not yet been artificially produced.

It seems very desirable to know, both upon chemical and geological grounds, the conditions necessary for their production, and especially in those forms which they assume in nature.

The metallic phosphates and arseniates—a group of salts which, almost without exception, are only known in the laboratory as gelatinous or pulverulent precipitates,—stand conspicuous among those native minerals, which we have hitherto been unable to obtain by artificial means in their crystalline forms.

I have recently attempted the crystallisation of some of these compounds, with a certain degree of success; and further, in the course of my experiments, I have succeeded in crystallising some phosphates, which, hitherto, have not assumed such a crystalline form, either naturally or artificially.

The process I employ is to add a soluble phosphate, or arseniate, to the solution of a salt of the metal, the phosphate or arseniate of which is required, in the manner hitherto adopted, but only in such limited quantity, that the mixed solution remains acid in its reaction, instead of alkaline, as occurs in the usual method of procedure. If the precipitate is long in appearing, it may occasionally be crystalline; if it comes at once it will be gelatinous, as usual, but in the course of a few hours—sometimes, however, a few days—it will be found crystallised throughout.

The essential features of this process are:—

1st. The maintenance of the precipitated metallic salt in its integrity, which is effected by having the surrounding solution feebly acid.

2nd. Allowing motion to the particles of these gelatinous precipitates, whereby they are amenable to the action of crystallising force; this is accomplished by keeping a little of the same phosphate in a soluble state in contact with them.

In this manner I have succeeded in crystallising the following phosphates and arseniates, which occur in this form in the natural state:—

* *Phosphate of Zinc*.—Hopeite, $(ZnO)_3PO_3 + 5H_2O$.

Phosphate of Cadmium.

Arseniate of Zinc.—Kottigite.

Arseniate of Lime.—Pharmacolite.

The following crystallised phosphates and arseniates produced do not occur as such in a natural state:—

Phosphate of Lime, $\text{CaO}_2\text{HOPO}_5 + 3\text{HO}$. This has the same composition as the amorphous precipitate, produced by adding a triphosphate to chloride of calcium, and then a little ammonia (the precipitate being air-dried); and it is isomorphous with the natural arseniate of lime above, *Pharmacolite*. It crystallises in the form of rhombs, and is acid to test paper.

Phosphate of Chromium contains 24 eqs. of water, and has probably the same constitution as Delvauxine, or hydrous phosphate of sesquioxide of iron, the iron being replaced by chromium; its colour is the same as that of chromalum, the substance used as the source of the chromium.

Phosphate of Silver. Only crystallised from its solution in acetic acid.

Phosphate of Baryta and Strontia are also easily crystallised. Those salts having formulæ attached have been analysed.

On reviewing these salts, it will be noticed that the copper, nickel, cobalt, and iron phosphates and arseniates are absent. Indeed, I have not been able to crystallise any of them in this manner; although I am aware that it has been affirmed that phosphate of nickel has been artificially crystallised. But I find that all these metallic phosphates, &c., are capable of forming double phosphates, &c., with phosphates of magnesia and ammonia. The metal may, I think, be looked upon as substituting one equivalent of magnesia in the common ammoniacal phosphate of magnesia.

I also find that phosphate of zinc forms a crystallisable compound with either phosphate of cobalt or nickel. It may be remarked here that the crystalline mineral, *Kottigite*, an impure arseniate of zinc, always contains a little of both these phosphates.

Lastly, it appears that crystalline precipitates are readily produced by contact of soluble phosphates with solutions of the metals cobalt and nickel, if a salt of ammonia is also present. These precipitates contain ammonia, in small quantity, but it appears to be an essential element in their composition, and not a mere accidental impurity; its quantity has not yet been determined.

The inferences I would draw from these results are:—

1st. That several of the crystalline, simple, natural phosphates and arseniates have not been produced as such directly; but that, in the first instance, compound phosphates or arseniates have formed. Magnesia and ammonia, singly or collectively, being the other members of the term. The magnesia and ammonia being afterwards gradually substituted by the metallic oxide. A continued supply of such metallic oxide to the compound phosphate or arseniate would almost certainly effect this, the metallic phosphates and arseniates being more insoluble than the alkaline ones.

2nd. This property of some of the metallic phosphates, &c., of combining with phosphate of magnesia and ammonia to form insoluble compounds, makes it very probable that several of these natural phosphates and arseniates may contain very appreciable quantities of ammonia or magnesia. At any rate, I think, with this property manifested, it would be well to examine rigorously this class of compounds for either of these substances.

These notes are, of course, merely preliminary, there being several points of interest left undiscussed, which can only be properly represented along with the results of future investigations.

PROPERTIES AND ESTIMATION OF ALBUMEN.

In a recent number, we alluded to a new work on Quantitative Analysis by Prof. Storer. To show our readers the complete and interesting way in which the work is done, we extract from the first sheet the article on "Albumen":—

Principle I.—Coagulability by heat.

Applications.—Estimation of albumen in alkaline solutions, such as urine and the serum of blood,

Method A.—Acidulate the solution slightly with acetic acid, and boil for several minutes. Collect the precipitate on a tared filter, wash thoroughly with warm water, and dry in a current of warm air at 110° or 115° , or, better, *in vacuo*, over sulphuric acid, until the mass ceases to lose weight. Care must be taken that the precipitate is thoroughly dried; for, as soon as the moisture has been driven from its surface, the mass acquires the consistence of horn, and forcibly retains the last portions of the water. The addition of acetic acid to the liquid is essential, in order that the albumen shall be precipitated completely; but no great excess of the acid should be employed, lest some of the albumen be dissolved by it. The precipitate thrown down from solutions thus acidulated is more flocculent, and less apt to clog the pores of the filter during the process of washing than that obtained without the addition of an acid.

To determine albumen in urine, place 50 to 100 c.c. of the clear urine (previously filtered, if need be) in a flask large enough to hold twice as much of the liquid. Heat the liquor gradually, with frequent shaking until the albumen begins to coagulate, at about 70° ; then throw a couple of drops of acetic acid into the flask from the end of a glass rod, and boil the liquor as above described (Neubauer and Vogel).

Method B.—Another method of estimating albumen in urine, devised by Heller (*Heller's Archiv. für Chem. und Microsc.*, 1852, p. 266, *et seq.*), is said to afford very accurate results, in spite of being indirect:—Evaporate 10 or 15 grms. of the urine to dryness over sulphuric acid, and weigh the residue. Weigh out another quantity of the same urine in a small flask; acidulate it slightly with acetic acid; boil until all the albumen is precipitated; and, after the liquid has become cold, place the flask upon the balance, and add to it, drop by drop, water enough to replace what has evaporated. Filter the contents of the flask, and evaporate a weighed portion of the filtrate to dryness over sulphuric acid. The difference between the percentage of residue left by the original urine and that obtained from the urine after the separation of the albumen gives the proportion of the latter ingredient.

Method C.—For comparing the quantities of albumen in any two different samples of urine, Dr. John Harley has adopted the following process:—Make three small filters from the same sheet of paper; cut down the two heavier to the weight of the lightest, and mark the filters, with a pencil, A, B, and C. Take 1000 grain-measures of urine A; and, having boiled it, pour it, while hot, upon filter A. Treat urine B in a similar way. Wash the contents of each of the filters with warm water until the last traces of adhering urine have been removed. Then pour upon the albumen an ounce of water containing 2 drops of nitric acid, and subsequently wash out the acid with water. The filter marked C is placed, in the first instance, between one of the other filters and the funnel, and is thus equally saturated with urine and acid, and equally washed free from both. All three filters are dried together; and the empty filter is used as a counterpoise in determining the weight of the albumen upon the others.

Properties.—Albumen, as it occurs in the state of solution in the animal economy, is combined, not only with water, but with minute quantities of certain saline and alkaline ingredients. When a solution of pure albumen is evaporated, *in vacuo*, at temperatures below 50° , there is left a light yellow, translucent mass of soluble albumen, which may be readily rubbed to a fine white powder. When treated with water, this residue swells up to a jelly, without, however, dissolving to any very considerable extent, unless a small quantity of an alkaline salt be present. By the action of most mineral acids, and of many other chemical agents (sometimes by mere contact with atmospheric air), this soluble modification of albumen is changed to the coagulated, insoluble condition.

Insoluble albumen, when recently precipitated and still moist, is a tough, white, opaque, flocculent solid, insoluble

in water, alcohol, ether, and most acids, when dilute and cold. When left moist in the air, it putrefies. It is somewhat soluble in hot acetic, tartaric, phosphoric, and strong chlorhydric acids. When boiled for a long time with water, it decomposes and dissolves. On being dried, it assumes a yellow colour, and becomes brittle and translucent, like horn. When soaked in water, after drying, it takes up about five times its weight of the liquid, and becomes soft and elastic.

Principle II.—Opacity.

Applications.—Estimation of albumen in aqueous and saline solutions.

Method.—Prepare a little trough of sheet-iron, with glass ends, as follows:—Provide three rectangular sheets of metal, one 7 c.m. square, the others 4 c.m. long by 2.5 c.m. wide. Bend the square sheet into the form of a V-shaped gutter, the upper edges of which are 1 c.m. apart. From each of the smaller sheets cut out wedge-shaped pieces of metal corresponding to the shape of the trough, so that, when the sheets are placed in an upright position, the V-shaped trough may fit into the cuts, and be supported as by feet. Place one of these supports near each end of the trough, and solder them to the trough. Cut out two V-shaped pieces of window glass, fitted to the trough, and cement them into the ends of the trough with Canada balsam, taking care to place the glasses parallel to one another, and to leave a clear distance of 6.5 c.m. between them. The glasses can be cemented the more readily in case a notch or groove be made upon the iron in the beginning to receive them. The metal of the trough should be painted with asphaltum varnish to protect it from rust.

As applied to the estimation of albumen in urine, the process of testing is as follows:—Filter the urine, in case it is not clear, acidulate it slightly with acetic acid, if it be not already acid, and proceed to determine how much the urine must be diluted to fit it for the test. To this end prepare several dilute solutions by mixing measured portions of the urine with water and boil each of the solutions in regular order, until one is found in which the albumen no longer separates in distinct flocks, but only as a milky cloud. It is a liquid thus clouded by the presence of fine particles of suspended albumen, which admits of being subjected to the test of opacity.

The best way of preparing these dilute solutions is the following:—By means of a little pipette graduated to 0.1 c.c., take up 6 c.c. of the urine and transfer it to a 100 c.c. flask. Fill the flask with water to the mark, shake the mixture thoroughly, pour the liquid into a beaker and leave the flask inverted in order that it may drain. Meanwhile pour 6 or 8 c.c. of the diluted urine into a test-tube of 20 or 25 c.c. capacity, heat the liquid to boiling, and afterwards cool it quickly by immersing the tube in cold water. In case the precipitate produced by boiling is so slight that the form of objects placed in strong daylight can be distinguished on looking at them through the liquid, the sample has been too much diluted, and the operator will at once proceed to prepare a more concentrated solution by mixing 12 c.c. of the original urine with water in the 100 c.c. flask. But in case the first solution was not transparent, it may be tested in the trough.

In testing, fill the trough two-thirds full of the cold boiled liquid, and look through the liquid at the flame of a burning candle in a darkened room. Repeat the experiment with other diluted samples of the urine until a point is reached where the shape of the flame cannot be distinguished, and only diffused light can be seen through the liquid, even when the candle is brought close to the trough.

In case the flame is visible through the first solution, the next trial must be made with a solution containing a few more per cents of urine than the first. But if the shape of the flame cannot be distinguished, the liquor of the subsequent trial must be more dilute, and so on methodically, until a liquid is obtained through which the reddish yellow cone of flame can only be seen by

looking with the strictest attention, as if it were in a thick fog. When this point is reached it is only necessary to add a trace more urine (0.1 or 0.2 per cent) in preparing the next diluted sample, in order that the flame may become completely invisible, and the operation be finished.

To find the percentage of albumen, divide the number 2.3553 by the number of c.c. of urine taken to prepare the dilute solution through which the flame could no longer be seen. This number 2.3553, is the mean of 35 experiments by Dragendorff, in which the results of the optical test were controlled by precipitating and weighing the albumen.

Precautions.—In looking at the flame, the trough should be held before the eye like a spy-glass, and moved forwards and backwards from a distance of 0.5 metre from the candle close up to the flame, while the instrument itself is continually pressed lightly against the eyebrow. Up to a certain point the last glimpses of the cone of flame can be seen more readily, in proportion as the trough is closer to the candle, but if the flame is too near the liquid, the latter is illuminated by a reddish yellow light, through which the flame is seen less readily. The chamber in which the operation is conducted, should always be dark enough that the yellow light of the candle may overpower the daylight.

In case albumen separates from a diluted liquor in small flocks, the liquor may often be made cloudy and fit to be tested by shaking it violently as soon as the flocks appear. Densely clouded liquids, on the other hand, may be used for preliminary, approximative tests, by mixing them with measured quantities of water. But the results of such experiments must always be controlled by testing samples of urine which have been diluted before boiling. Better results can always be obtained by boiling weak solutions of albumen than by boiling comparatively strong solutions and mixing the cloudy liquor with water.

Instead of the 100 c.c. flask above prescribed, a 50 c.c. flask may be used, but rather more accurate results can be obtained when the larger volume of liquid is operated upon. The pipette employed must be graduated to 0.1 c.c. so that quantities of liquid as small as 0.05 can be measured with it.

The chief difficulty of the process is found in endeavouring to properly acidulate the original urine. Many samples of albuminous urine yield no precipitate, or only a comparatively feeble precipitate on boiling, when too strongly acidulated with acetic acid, and, in like manner, less albumen is obtained by the optical test than by the method of precipitation, in case the acid reaction of the urine is indistinct. It is important that the urine should be kept in a cool place, in order that it may be as fresh as possible when tested.

The original urine need not be filtered unless it contains a distinct precipitate. Urine that is merely cloudy will usually become clear when mixed with much water. Some samples of albuminous urine, however, become cloudy when treated with a few drops of acetic acid or with five or ten times their volume of pure water, and it is precisely this kind of urine which is least readily tested by the optical method. Special care must be exercised in adding acid to such urine, since the presence of a trace of acetic acid in excess may present the appearance of any precipitate on boiling. The cloudy solution (paralbumen) produced on mixing the urine with water, need not be filtered. The mixture should be boiled at once, as if it were clear.

The process is easy of execution, and is said to yield very accurate results, excepting perhaps those kinds of urine which become cloudy on the addition of acetic acid. Ordinarily, no more than five or six of the diluted samples of liquid have to be tested in order to hit the point of obscuration, so that the determination will be finished in the course of half an hour.

The several experiments of the series above mentioned agreed with one another in most instances to the second

decimal place. Only three experiments out of the thirty-five differed more than 0.1, and only 11 more than 0.05, so that 21 of the trials agreed to 0.05 per cent. (Alfred Vogel, *Zeitsch. analyt. Chem.*, 1868, vol. vii., p. 152).

Principle III.—Power of rotating the plane of vibration of a ray of polarised light.

Applications.—Estimation of albumen in aqueous or saline solutions, such as urine and the serum of blood.

Method.—When a ray of polarised light is made to pass through a column of albumen solution enclosed in a tube, it is found that the plane of polarisation is rotated to the left, and that the angle of deviation is proportional to the length of the column of liquid. In like manner, when a tube of any given length is successively filled with solutions containing different quantities of albumen, the angle of deviation is found to be proportional to the amount of albumen in the liquid.

An apparatus, known as Soleil's Albuminometer, used for measuring the rotatory power of albumen, resembles the ordinary Saccharimeter, with the exception that, in place of the Nicol's prism there used as the analyser, a double refracting prism is employed, cut in such manner that only a single image shall appear in the field of vision. An intense white light, such, for example, as that of a petroleum lamp, is needed. The lamp is placed in a blackened box provided with a reflector, which throws the rays of light upon a movable lens, by which they are concentrated before reaching the apparatus.

After the lamp has been lighted and placed in front of the apparatus, put a piece of red glass in front of the polarising prism in the path of the luminous rays, and turn the analysing prism until the luminous image has completely disappeared. The zero point of the apparatus having thus been determined, fill the tube with the solution to be tested, place it in the apparatus, and leave the liquid at rest during some minutes. On again looking into the apparatus it will be seen that, by virtue of the rotatory power of the liquid in the tube, the luminous ray has again become visible, and it will be found that the index of the apparatus must be turned through a certain number of degrees in order to again extinguish the ray. But by counting the number of degrees and minutes between the two points of extinction, it is easy to determine the amount of the rotation and to estimate therefrom the proportion of albumen in the liquor.

It is important to exclude external light as completely as possible; to make several observations with each sample of liquid, and to read the divisions of the circle and vernier carefully, best with a good lens.

In case serum of blood is to be tested, about 1 grm. of sulphate of sodium should be added to each 100 grms. of the liquid, and the mixture filtered immediately, in order to separate blood globules and other suspended particles. The purpose of the sulphate is merely to facilitate the filtration; in the case of urine none of it need be added. The yellowish orange colour exhibited by serum when viewed in thin layers, becomes distinctly red when seen in a long column like that in the tube of the albuminometer. In general, however, this colouration is not intense enough to do any harm; it simply obviates the need of using the red glass, for, like the latter, it only permits the passage of red rays.

In a series of fifty experiments upon blood serum, Becquerel found that the deviation of the plane of polarisation varied between $4^{\circ} 30'$ and 9° , or, on the average, $7^{\circ} 30'$. In general, the deviation oscillated between 7° and 8° . The corresponding quantities of pure dry albumen were from 4.86 to 9.44 per cent. From these and like observations, it has been calculated that, with a column of liquid 20 c.m. long, each minute of deviation corresponds to 0.18 grm. of albumen. (Becquerel, in Robin and Verdeil's *Chimie Anatomique*, 1853, iii., 316.)

Principle IV. Specific Gravity.

Applications.—Estimation of albumen in urine.

Method.—Take the specific gravity of the urine and note the temperature of the liquid when the observation

is made. Acidulate a quantity of the urine with acetic acid, place the liquid in a flask provided with a perforated cork carrying a vertical glass tube, and boil it until all the albumen has separated in the insoluble state. Cool the boiled urine to the temperature at which the specific gravity of the original urine was determined, and take the specific gravity of the clear filtrate. Multiply the difference between the two specific gravities by 210, in order to obtain the percentage of albumen in the sample. In a series of thirteen experiments, the least error was 0.005, and the greatest 0.056. (Lang and Haebler, *Zeitsch. analyt. Chem.*, 1868, vii., pp. 513, 514.)

An article on the estimation of albumen, by gravimetric and volumetric methods, has been published by C. Boedecker, in Henle and Pfeuffer's *Zeitschrift für rationelle Medicin*, Zurich, 1859, v., 320.

ON THE ANILINE OR COAL-TAR COLOURS.*

By W. H. PERKIN, F.R.S.

(Continued from p. 54.)

ANILINE-BLUE, or "bleu de Lyon," is supplied to consumers as a coarse powder having a coppery lustre, or in alcoholic solutions; it is nearly insoluble in water, and has to be dissolved in alcohol before it is added to the dye bath.

The nature of this blue has been determined by Dr. Hofmann. It is found to contain, like magenta, a colourless base, becoming blue only upon combining with acids. Dr. Hofmann has shown this base to contain $C_{18}H_{13}N_3$, and has called it "triphenylrosaniline." Like rosaniline, it becomes colourless when treated with nascent hydrogen, forming a new base, giving colourless salts, as leucaniline. The composition is $C_{18}H_{13}N_3$.

The insolubility of aniline blue in water has been found a great drawback to its use, because when employed for dyeing it is thrown out of solution in the dye bath, and then mechanically adheres to the goods, so that it afterwards rubs off.

Mr. Nicholson has, however, discovered a process for rendering this blue perfectly soluble in water. His process closely corresponds to that employed to render indigo permanently soluble. This, it will be remembered, is effected by subjecting indigo to the action of concentrated sulphuric acid, whereby a sulpho-acid is produced.

Mr. Nicholson has found that aniline blue, when treated by a similar process, also forms a sulpho-acid, perfectly soluble in water, and forming with alkalis nearly colourless solutions. These, however, when decomposed by acids, change back to the original blue.

This soluble blue is now much used for silk dyeing, but by dyers it is not thought to be so fast as the normal compound. By some modification of the process just described, Mr. Nicholson has obtained another soluble blue, commercially known as "Nicholson's blue." This is now very extensively employed in Great Britain for wool dyeing, but its application does not appear to be well understood in France and Germany, so that its use there is not so great as in our own country.

If a salt of rosaniline and aniline be heated together, and the process stopped before aniline blue is produced, the resulting product when treated with dilute acid gives a colouring matter which has been called "violet imperial." This was at first supposed to consist of a mixture of blue and magenta, but recent research has shown it to consist of intermediate products. Very large quantities of this colouring matter have been used, but its consumption is now rapidly falling off, owing to the introduction of new violets, about to be described. A few months after the discovery of aniline blue, another colouring matter, called the "bleu de Paris," was obtained by MM. Persoz, De

* The Cantor lectures, delivered before the Society of Arts.

Luyne, and Salvétat. These chemists found that when aniline was treated with tetrachloride of tin for thirty hours to 180° C. in a sealed tube, neither a red nor a violet, but a very pure blue was produced. This colouring matter is generally described as being identical, or probably identical, with the bleu de Lyon. These blues are, however, widely different in their chemical nature, as the bleu de Paris is easily soluble in water, and crystallises freely in needles of a blue colour, with a coppery reflection. It consists of the hydrochlorate of an organic base, which is precipitated from its solution by alkalies as a purplish blue powder; it dyes silk readily, and retains its blue colour by artificial light. It is remarkable that the discoverers of the bleu de Paris do not seem to have observed its difference from the bleu de Lyon.

I have prepared some of this product with a view to its examination, but hitherto have been prevented from determining its composition. I hope to do so soon.

The bleu de Paris is, unfortunately, difficult to prepare in large quantities, and has never been introduced commercially.

The recognition of the nature of the bleu de Lyon, by Dr. Hofmann, led him to study the action of a class of substances upon rosaniline, known to chemists as the iodides of the organic radicals; this investigation resulted in the discovery of the brilliant colours known as the Hofmann violets, and of which so many shades can be obtained, from a very red purple to a nearly pure blue.

The substances generally used for the preparation of the Hofmann violets from rosaniline are the iodides of methyl and ethyl; the iodide of methyl differs from that of ethyl in a practical point of view, in being rather quicker in its action; it is also more volatile. Both these substances contain a remarkable element called iodine. This body is found in sea-water and sea-weed; its aspect is very similar to that of a metal; one of its characteristic properties is that, when heated, it volatilises and produces a beautiful purple coloured vapour, and here we find how dangerous a little knowledge is when relied upon. When the iodide of ethyl, which, as I have told you, contains iodine, was introduced for the preparation of the Hofmann violets, it was stated in some of our periodicals or daily papers, I do not remember which, that chemists had at last succeeded in fixing the colour of iodine, whereas, the iodine has nothing whatever to do with the colours produced with the iodides of ethyl and methyl, but is simply an instrument in bringing about the change which takes place in their formation; moreover, these colours can be equally produced without using iodine at all. It is unfortunate that the popular reports upon scientific matters are generally so utterly untrustworthy. One of the most remarkable reactions of iodine is the blue violet colour it gives with a solution of starch; this is used as a test for its presence when in the free condition, and is remarkably delicate; it is of no use as a colour, as it is instantly decomposed when heated. To prepare iodide of ethyl, ordinary alcohol is treated with iodine and phosphorus; the operation has to be conducted with care, as iodine reacts upon phosphorus with great energy; usually the alcohol and phosphorus are placed in a retort, and the iodine added very carefully, and in small quantities at the time. The mixture is then distilled, and the distillate mixed with water, which causes the iodide of ethyl to separate as a colourless heavy oil. Iodide of ethyl is very volatile, boiling at 70° C.; it has an ethereal odour, and when pure is colourless and transparent; it contains no less than 81 per cent of iodine. Iodide of methyl is prepared in exactly the same manner as that of ethyl, substituting wood naphtha, or methylic alcohol, for ordinary alcohol; it contains a still larger quantity of iodine than the iodide of ethyl, viz., 89 per cent.

For the preparation of these substances on the large scale, special apparatus has been devised, and sometimes amorphous or red phosphorus is substituted for the ordinary kind; but I shall not have time to enter more

fully into this subject. To produce the violets, Dr. Hofmann heats pure rosaniline with iodide of ethyl, or methyl and methylated spirits of wine, in a cast-iron digester, closed air-tight, with a lid fastened down with screws. A process very similar to this is sometimes employed, and consists in using a salt of rosaniline, caustic alkali, iodide of ethyl, and alcohol. But in Germany the ordinary hydrochlorate of rosaniline is employed with alcohol, or wood spirit and iodide of ethyl, and is found to work very successfully. By employing the rosaniline itself a lower temperature is required for the formation of violet than when using its salts; in fact, I have found that a mixture of iodide of ethyl and rosaniline react even at the ordinary temperature if left in contact for a few days, and produce a red shade of violet.

On the large scale, Hofmann's violet is generally prepared in deep cast-iron vessels, surrounded with a steam jacket, and provided with a lid having a perforation, closed with a screw plug. This lid can be firmly fastened down with screws, the joint being made with a vulcanised india-rubber washer. This apparatus is charged with a mixture of hydrochlorate of rosaniline dissolved in alcohol or wood spirit, and iodide of ethyl or methyl, in proportion according to the shade required. After the apparatus is closed the steam is allowed to enter the steam jacket, and the heating continued for five or six hours; the plug is then removed from the lid of the apparatus, and the alcohol or unused iodide of ethyl distilled off. The resulting product is dissolved in water, filtered, and precipitated with chloride of sodium, but sometimes it is first treated with caustic alkali, to remove all the iodine, so that it may be recovered. Thus obtained, the colouring matter is of a golden lustre if of a blue shade, and of a greenish if of a red shade.

Like all the other colours we have considered, the Hofmann violets are nearly white organic bases, their composition differing according to the shade of colour, thus:—

A red shade is composed of ..	$C_{22}H_{23}N_3$
A red violet shade of	$C_{24}H_{27}N_3$
A very blue shade	$C_{26}H_{31}N_3$

The colours of the Hofmann violets are remarkable for their brilliancy, but, unfortunately, they do not resist the action of light so well as might be desired; it is remarkable, however, that the regard for fastness seems to have given way to the desire for brilliancy.

In the early days of coal-tar colours fastness was so much talked about, that when magenta was first introduced it was thought by some that it would not be largely used—how different has it proved to be. Although not very fast upon cotton, the Hofmann violets are sufficiently so for woollen and silk goods, as colours always resist the light better when applied to animal fibres.

In the formation of Hofmann violets we see that rosaniline, when treated with iodide of ethyl, becomes blue, the red being converted into violet; but with mauveine, the base of the mauve, exactly the reverse takes place, the mauveine being converted into a much redder shade with iodide of ethyl. The colouring matter produced from mauveine and iodide of ethyl is commercially known as "dahlia;" the colour is intermediate in shade between aniline purple and magenta. This colouring matter possesses the same character for fastness as the mauve, and also gives the same reactions with acids; unfortunately it is rather expensive, and has, therefore, not been very extensively used.

Lastly, there has been a process proposed for the production of colouring-matters similar to the Hofmann violets, by first converting the aniline into ethylaniline, a base previously discovered by Dr. Hofmann. It is found that by substituting this base for aniline, in some of the processes which have been employed for the manufacture of magenta, the ethyl-aniline yields purple or violet colouring-matters.

This process has been patented by MM. Poirier and Chappat, but the reaction appears to have been first observed by M. E. Kopp. From the great similarity of these colouring matters to the Hofmann violets, I need not enter into any lengthened description of their properties.

Sea-water contains, besides iodine, another remarkable element called bromine; it is a liquid giving off very irritating orange-coloured vapours. This remarkable body yields, with many hydro-carbons, a great variety of compounds. With ordinary turpentine, it acts with great violence; but if the action be moderated by the presence of a large quantity of water, a thick viscid oil is obtained. This body was examined by Mr. C. Greville Williams, who found it to possess the formula— $C_{10}H_{15}Br_3$.

I have found that this substance, when heated with a solution of magenta in methylated spirits, produces a purple colouring matter of great beauty, commonly known as the Britannia violet; it is very extensively employed for dyeing and printing, and can be produced of any shade, from purple to a blue violet.

The Britannia violet possesses the golden green lustre so common to all the aniline colours. It is easily fusible, amorphous, and very soluble in water.

In my last lecture I showed you the great intensity of the mauve dye. I will now make a few experiments to illustrate the great intensity of some of the colouring matters we have been considering this evening.

I have here some screens of white paper, on which I have dusted a very small quantity of the solid colouring matters,—so small a quantity that I dare say you can scarcely discover its presence. If I now project spirits of wine upon these screens, so as to dissolve the colours, you will see their remarkable intensity.

Let us now consider for a moment the great rapidity with which the discovery of new coal-tar colours followed that of the mauve or aniline purple.

Aniline purple was discovered in 1856; three years afterwards, in 1859, the magenta was introduced. In 1861 we had the aniline blue; in 1863 the Hofmann violet; and in 1865 the Britannia violet. Thus we see that all these colours have not only been discovered, but introduced commercially, in a period of less than ten years.

We have now reviewed the principal coal-tar colours, but there still remain some important ones for our consideration next lecture; and although some of these are not at present largely used, yet it is to them, perhaps, that we may look for the future development of this branch of industry.

(To be continued).

BURETTE FOR VOLUMETRIC ANALYSIS.*

By J. BLODGET BRITTON.

THERE has been in constant use, for the last four years, at the Iron Masters' Laboratory, in determining iron in metals and ores, a very convenient and serviceable burette.

Figures 1 and 2 represent two of the kind, but of different patterns, mounted on walnut wood stands; the former is for metals, and the latter, of smaller capacity, for ores.

Securely fastened to the upright, B, is a graduated tube, A, having its lower part drawn out in the usual manner, but bent outwards at an angle of about 25° . E is a piece of cork rivetted into a sheet-steel spring, D, which presses tightly, by means of the latter, against the vent of the tube. C is a thumb-screw passing through the frame and bearing against the spring.

The tube of Fig. 2 has a capacity of 100 c.c. and is graduated into tenths, or 1000° ; but that of Fig. 1 has a capacity of 150 c.c. and is graduated into 20ths, though only at its lower and narrow part.

Modes of Operating.—Place a small narrow-necked funnel in the tube as shown by the figures; pour in the solution to be used until it quite reaches the funnel, and then remove the latter to carry away any floating bubbles; turn the thumbscrew and bring the top line of the solution exactly to the 0 line of the scale; stop the flow, and afterwards touch the point of the cork with a glass rod to take from it any adhering drop. The instrument is then ready

for use. By means of the thumbscrew the dropping may be controlled with *extreme nicety* or *instantly stopped*. Cork, after a little use, becomes quite inert towards permanganate of potash. The occasional application of some pure tallow to the end of the tube and cork will be quite effectual in preventing any of the fluid from running upwards by capillary attraction.

For every day use in the laboratory, as well as for very accurate determinations, I think this burette will find favour.

University of London (First B.Sc. Examination).—The following are lists of the candidates who have passed the recent examinations:—*Pass Examination*: First Division—Philip Herbert Carpenter, University College and Royal School of Mines; Thomas Hick, B.A., private study; John Landor Lowe, King's College; Leonard Lyell, University College; Bernard Mathias Simon Roth, University College; Robert Forsyth Scott, University College. Second Division—Charles Stuart McLean, B.A., Wesleyan College, Taunton; James Monckman, private study; Henry Elthington Price, University and Regent's Park Colleges; William Watson Rowland, B.A., University College.

* Communicated by Prof. Morton. From advance-sheets of the *Journal of the Franklin Institute*.

ROYAL INSTITUTION OF GREAT BRITAIN.

Notes of a Course of Seven Lectures on Electrical Phenomena and Theories. By Professor TYNDALL, LL.D., F.R.S.

(Continued from vol. xxi., p. 272.)

Electro-Chemistry.—Chemical Actions in the Voltaic Cell: Origin of the Current.

188. Philosophers suppose matter to be made of elementary parts, called atoms, which are practically indivisible.

189. The elementary atoms can be caused to unite to form compound atoms, which are called molecules.

190. Thus, water is formed of the combination of the atoms of oxygen and hydrogen; common salt is formed of union of atoms of chlorine and sodium; potash is formed by the union of the atoms of potassium and oxygen; the sulphuric acid, also, which we employed to acidulate our water is formed by the union of atoms of sulphur with atoms of oxygen.

191. When, as in our first experiment, two strips of zinc and platinum are dipped into acidulated water, the zinc, as we know, exerts a very strong attraction on the oxygen of the water. When the strips are united, this attraction triumphs; the oxygen unites with the zinc, and a voltaic current is established.

192. The oxide of zinc here formed combines with the sulphuric acid and forms sulphate of zinc.

193. By this removal of the oxide from its surface, the zinc is kept constantly clean, and thus enabled to attract other atoms of oxygen from the surrounding liquid. During this process the zinc gradually dissolves, and as long as this continues the electric current will flow. In fact, it is the constant dissolution of the zinc that maintains the permanent current.

194. The hydrogen of the water, as we have seen, escapes as a free gas from the surface of the platinum, which, unlike the zinc, is not dissolved.

195. We are not yet quite clear as to the precise way in which the electric current is supported by the solution of the zinc, but the following facts and speculations ought to be known to you.

196. When two different metals are brought into contact, with no liquid between them, one of them charges itself with positive and the other with negative electricity. We have here the famous "contact force" which Volta and his followers considered to be the urging power of the voltaic current.

197. But the generation of heat, and the performance of mechanical work, by the mere contact of two metals, would be equivalent to a perpetual motion. It would be at variance with the law which requires, for the production of any power, an equivalent consumption of some other power.

198. It is, however, a fact, that, when two different metals touch each other, the positive electricity resorts, by preference, to one metal, and the negative electricity to the other; the two electricities are, as it were, attracted differently by the two metals.

199. This difference of attraction, however, only causes a momentary re-arrangement of the two electricities, which pass, when the contact is made, into a new condition of equilibrium. As long as the contact continues, this equilibrium is not disturbed; there is no continuous current.

200. We may regard the distinct atoms which enter into the molecules of a compound as charged in a similar manner. For example, the atoms of hydrogen and oxygen, when they unite to form a molecule of water, may be looked upon as charged like the two touching metals. This would be the case if the atoms, like the metals, possessed different attractions for the two electricities.

201. When strips of zinc and platinum are plunged in such a liquid, the positively-charged atom will turn towards the one metal, and the negatively-charged atom towards the other.

202. But, unless the metals touch each other, electrical equilibrium immediately sets in, a constant state of electric tension being set up at the free ends of the two metals.

203. The electricity at the ends may be permitted to flow into a condenser, and may be thus stored up; such a condenser may then be discharged through a covered wire which passes round a magnetic needle, a deflection of the needle being thus produced.

204. Thus, in Davy's experiment with his large voltaic battery, wherewith he charged his battery of Leyden jars, the latter, after having been charged, might be discharged through a galvanometer, a magnetic deflection being thus produced.

205. But the metals, once relieved of their charge, would immediately re-load themselves with electricity, and might be again employed to charge a Leyden battery, and to produce a deflection of a magnetic needle.

206. At no moment during this process the battery circuit would be complete; still we should have a succession of magnetic actions similar to those observed with a closed circuit.

207. In fact, in the closed circuit the solution of the zinc incessantly removes the charged surface of that metal by dissolving it away, and enables the zinc to take a fresh charge; an incessant effort, never fully satisfied, is made to establish electric equilibrium; the incessant renewal of the effort maintains the electric current.

Chemical Actions at a Distance: Electrolysis.

208. Thus, then, in the cell where the voltaic current is generated chemical action occurs. We have, on the one hand, the decomposition of the water, and on the other the combination of the zinc with the oxygen and the sulphuric acid.

209. But a voltaic current can also produce chemical action at a distance from its place of generation. This discovery, as stated in Note 127, was made in the year 1800, by Nicholson and Carlisle.

210. We cannot decompose water by a single voltaic cell; but, when two or more cells are united to form a battery, the current from such a battery, when sent through acidulated water, tears asunder the united atoms of oxygen and hydrogen.

211. The oxygen is set free at the place where the current enters; the hydrogen is set free at the place where the current quits the liquid. If the direction of the current be reversed, the oxygen and hydrogen instantly change places.

212. It must be clearly borne in mind that the direction of the current, as already defined, is the direction in which the positive electricity moves. Knowing, therefore, the places at which the oxygen and hydrogen are liberated, we can infer with certainty the direction of the current through the liquid.

213. For every volume of oxygen liberated in the decomposition of water by a voltaic current, two volumes of hydrogen are set free.

214. Electro-chemical decomposition is called *electrolysis*; and the compound liquid decomposed by the electric current is called an *electrolyte*.

215. The electric current formed a powerful means of analysis in the famous experiments of Sir Humphry Davy, in 1807.

216. By operating with the current upon ordinary potash, Davy found the base of this substance to be a metal of exceeding lightness, and with an extraordinary appetite for oxygen. When placed on water, it floated on the liquid, and combined with its oxygen. By the heat thus generated, the liberated hydrogen was caused to burst into flame. When a globule of the metal was placed on ice, it burned with a bright flame, and the hole made by the heat was filled with a solution of potash.

217. Soda, treated in the same manner, also yielded a metal resembling that of potash. Thus Davy, by the use of the voltaic current, decomposed the alkaline earths, and greatly expanded our knowledge of chemistry.

218. To obtain these effects, it is necessary to bring the potash and the soda to a state of fusion by heat. In the solid state they are non-conductors of electricity. In fact, the molecules, when rigid, cannot turn in the manner indicated in Note 201. To conduct the current, it is necessary that they should thus turn and be decomposed.

219. When a current is sent through a solution of common salt, it decomposes both the water and the salt. The chlorine of the salt, in company with the oxygen of the water, appears where the current enters the liquid. The sodium of the salt, in company with the hydrogen of the water, appears where the current quits the liquid.

220. Chlorine possesses powerful bleaching properties; and, if the solution of salt be coloured with indigo or litmus, the presence of the chlorine is declared by the destruction of the colour.

221. When a current is sent through a solution of iodide of potassium, the brown substance, iodine, is set free where the current enters, while the metal, potassium, is set free where the current quits the solution. The experiment may be made by moistening bibulous paper with the dissolved iodide.

222. In electrolysis, it is usual to immerse two plates of platinum, or of some other suitable substance, in the liquid to be decomposed, and to send the current from plate to plate. The plate at which the current enters the liquid is called the positive electrode; the plate at which the current quits the liquid is called the negative electrode. Without the liquid, these electrodes would, as we have already learned, charge themselves with positive and negative electricity.

223. But, inasmuch as electricities which attract each other are of opposite qualities, the substance which is liberated at the positive electrode is called the electro-negative constituent, while the substance liberated at the negative electrode is called the electro-positive constituent of the liquid.

224. Thus, in the examples above given the oxygen, chlorine, and iodine are the electro-negative elements; the hydrogen, sodium, and potassium being the electro-positive elements.

225. The terms electro-positive and electro-negative are, however, relative, for a substance may be electro-positive in one combination, and electro-negative in another.

226. If an electric current be conducted through a solution of sulphate of soda, it separates the sulphuric acid from the soda; the presence of the acid may be proved by its turning a vegetable colour red.

227. When nitrate of silver or acetate of lead is decomposed by a voltaic current, crystals of silver, or of lead, are deposited on the negative electrode.

228. The chemical actions of the electric current, some examples of which are here given, constitute what is called electro-chemistry.

229. Electro-plating and gilding, and the electrotype process, are important applications of electro-chemistry. Here, a chemical compound, containing gold, silver, or copper, is decomposed by a voltaic current, the metal being deposited on the surface intended to be coated with it.

230. If the surface on which the metal is deposited have a design engraved upon it, the lines of the engraving are accurately filled by the metal, which, when the deposit is thick enough, may be detached, a perfect copy of the design being thus obtained.

Measures of the Electric Current.

231. The *tangent-compass*, devised by Weber, consists of a vertical ring of brass or copper, in the centre of which swings a small compass-needle. The ring being placed in the magnetic meridian, the needle is deflected when a current is sent round the ring. The strength of

the current can be proved to be proportional to the tangent of the angle of deflection; hence the name of the instrument.

232. The *voltammeter* is an instrument devised by Faraday to measure the strength of an electric current. It consists of a graduated tube, which receives and measures the quantity of gas generated by the current in a given time.

233. The strengths of a series of currents measured by the voltammeter are accurately proportional to the same strengths measured by the tangent-compass. Placing a tangent-compass and a voltammeter in the same series of circuits, the tangents of the angles observed in the one case are accurately proportional to the quantities of gas generated in the other.

(To be continued.)

NOTICES OF BOOKS.

Paris Universal Exposition, 1867. Reports of the United States Commissioners. The Progress and Condition of Several Departments of Industrial Chemistry. By J. LAWRENCE SMITH, United States Commissioner. Washington: Government Printing Office. 1869.

WE owe to the politeness of the United States Government the receipt of this useful report from the hand of a gentleman of high scientific attainments, who has evidently been thoroughly master of the subjects he undertook to report upon. These subjects are:—the manufacture of sulphuric acids; soda and salts of soda; potash and its compounds; ammonia, baryta, magnesia, and alumina; chlorine, fluorine, manganese, and carbonic acid; industrial production of oxygen, hydrogen, and other elements; manufacture of illuminating gas from coal, and the utilisation of the waste products; stearic acid industry; description of the plates.

This is the bare enumeration of the headings of eight chapters, which are preceded by an introduction, from which we give a quotation. After having briefly referred to the importance of class 44 of the exhibition above alluded to, that class embracing chemical products and chemical processes, the eminent author says:—"Industrial chemistry links itself with every modern art in such an intimate manner, that were we to take away the influence and results of chemistry, it would be almost like taking away the laws of gravitation from the universe; industrial chaos would result in one case, as material chaos would in the latter. No one can paint in too vivid colours the sum of indebtedness the civilised world is already under to the chemist, and no enthusiast can transcend in his wildest speculations what we are yet to realise. The chemical arts in their strictest sense do not simply aid other arts, but they keep in activity a vast amount of capital, and consequently give employment to a large number of individuals, skilled and unskilled." As regards the scope of this book, the author informs us that it is not the province of this work to detail the general character of the articles exposed by different exhibitors, except so far as this or that article may possess some special merit. The author of this work has very successfully brought out an excellent book, from which it is our intention to reproduce some articles in full. The chapters on the manufacture of sulphuric acid, soda, and salts are very complete and concisely written treatises on these subjects.

The Royal Polytechnic.—Professor Pepper has lately introduced an amusing entertainment, in which he exhibits the effects, and describes the various modes, of causing ghostly representations of human beings to perform their mysterious movements. His highly interesting lecture, entitled "Sand and the Suez Canal," and a musical entertainment by George Buckland, Esq., are still numbered amongst the attractions.

CORRESPONDENCE.

"ROCHAGE" OF CAST-IRON.

To the Editor of the Chemical News.

SIR,—In the CHEMICAL NEWS, vol. xxi., p. 298, you give a brief notice of a paper on this subject by M. H. Caron. This curious phenomenon is well known to those engaged at blast furnaces. The sparks are known by the workmen as "jumpers," and their presence is usually held to indicate an approximation to white-iron. These sparks are absent during the running of grey-iron from the furnace, and only begin to make their appearance when the iron is about No. 4, the usual degree of greyness preferred in South Staffordshire for puddling. The sparks are best observed during the running of white-iron from the furnace, especially if the molten metal is not very fluid, at which times I have frequently observed a vast number produced, particularly in the channel; and sometimes, after the pigs have "set," little jets of sparks are continuously discharged for many minutes, which discharge is accompanied by a hissing sound.

M. Caron's view may probably be correct, but I am inclined to attribute the production of these sparks to the combustion of carbon, and not of iron, as there is an entire absence of the peculiar scintillations displayed by burning iron. Yet one would almost be inclined to believe that grey-iron, which is supposed to contain uncombined carbon, would be more likely to exhibit this appearance than would white- or mottled-iron. Yet, in grey-iron, and even in over-grey, or "Kishy" iron, there is an entire absence of these sparks.

I should be glad to be enlightened by some of your readers upon this curious point—one of the many phenomena of curiosity and interest that are so plentiful at blast-furnaces.—I am, &c.,

T. B.

Stourbridge, July 29, 1870.

MISCELLANEOUS.

Quekett Microscopical Club.—The Fifth Annual General Meeting of this Club was held on Friday evening last, July 22nd, at University College, Gower Street; Peter LeNeve Foster, Esq., President, in the chair. According to the Annual Report of the Committee, which was read, the Club still maintains its popularity and success. It numbers over 500 members, and meets for the prosecution of microscopical enquiry and discussion twice a month throughout the year. Mr. Peter LeNeve Foster in vacating the presidential chair, which he had so ably filled during the past year, delivered his valedictory address, in which he called attention to various open questions in microscopical science, and which were fields well worth the labour required for their investigation, and which, he considered, the members might undertake the study of with pleasure to themselves, and advantage to the world at large. Professor Lionel S. Beale, F.R.S., was elected President for the ensuing year, and Messrs. Henry Lee, F.L.S., Arthur E. Durham, F.R.C.S., Peter LeNeve Foster, M.A., and Dr. Robert Braithwaite were elected Vice-Presidents; while Messrs. Allbon, T. W. Burr, W. M. Bywater, and Charles F. White were elected to fill four vacancies on the Committee. The proceedings then terminated in a *conversazione*.

Diamonds.—At a recent meeting of the New York Lyceum of Natural History, Professor T. Egleston, jun., exhibited a fine suite of crystallised diamonds, including about all of the known forms in which this gem is found. They varied in colour, as well as form, and many were curiously distorted, as well as twins. The distortions of

this mineral are very numerous, and of great interest to the mineralogist, as well as dealer in gems. The cube is always opaque. Even if the crystalline form were not well marked, yet a diamond could be told from its peculiar cleavage, which was unmistakable. This cleavage was taken advantage of often in preparing gems for cutting; but sometimes it could not be employed, on account of the shape of the stone, which would be injured in such cases.

An Improvement in Galvanic Batteries.—Mr. W. Poole Levison, of Cambridge, Mass., in a letter to the *Journal of the Franklin Institute*, says:—"In the spring of 1869, while making use of a small bichromate of potash battery, I discovered that the addition of nitric acid to the mixture of potassic bichromate and sulphuric acid, contained in its porous cups, conferred upon it the virtue of *steadiness*, without involving the evolution of annoying fumes. For over two months, during last summer, I had in almost constant action a combination of twenty-three large Bunsen cells charged with dilute sulphuric acid and the triple mixture mentioned, and "set up" openly upon the floor of my room. Not only did I work about it with perfect comfort, but left choice brass instruments in its immediate neighbourhood with impunity. Its energy never fluctuated, but after remaining for some time steady, declined, precisely as if the electro-negative plates were bathed in nitric acid only. To a cooled mixture of potassic bichromate solution and sulphuric acid (perhaps preferably in atomic proportions) add *nitric acid*. The proportion of nitric acid may be greatly varied, as its office is merely to transfer oxygen."

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "*Jahresberichte*."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, July 25, 1870.

This number contains the following papers relating to chemical-physical and collateral sciences:—

Observations on some Peculiarities of the Soil of the Landes.—M. Faye.—The author describes, in a lengthy paper, a peculiar sub-soil, locally known (in the *Départements des Landes*, and a portion of that of *La Gironde*) as *allios*. This is a layer of a peculiarly-agglomerated sand, intermingled with small pebbles, and containing organic matter, as well as oxide of iron. It (the *allios*) is met with at a depth of about 1 metre below the surface; and above, as well as below it (its thickness hardly ever exceeding from 1 to 2 metres, and generally less), is found the loose sand which, in former years, was constantly blown about by the winds, but is now retained in its place by the plantations of the *pinadas* (*Pinus maritima*). The author ascribes the origin of these *allios* to the fact that, during winter and early spring, these extensive plains (the *départements* above named are the largest in surface of all the French *départements*) are inundated by rain-water, which, being slowly absorbed by the soil, forms (at the depth already mentioned), in consequence of the matters it contains in solution, and by evaporation, a cement which causes the agglomeration of the underlying sandy sub-soil. In many parts of the barren moors of the Netherlands and Hanover a similar sub-soil occurs, being locally known as *oerbanken*; they often contain the marsh-iron ore in workable quantity.

Analysis of a Schistose Rock Impregnated with a Carbonaceous Matter.—H. Sainte-Claire Deville.—The sample here alluded to is a portion of one which was presented to the Academy by MM. Ravizza and Colomba. The author found that, on being ignited in a closed crucible, this substance loses, as volatile matter, 9.14 per cent. On being further ignited with exposure to air, the quantity of carbonaceous matter burnt off amounts to 0.22 per cent; leaving 90.64 per cent of ash, consisting, in 100 parts, of—Silica, 56; alumina and oxide of iron, 26; lime and alkalis, 18. The mineral, therefore, is simply a schistose rock, impregnated with bituminous matter.

Recent Observations on the Spectra of Various Types of Stars.—A letter from the Rev. Father Secchi, S.J., illustrated with diagrams.

Restoration of a Conically-Shaped Sun-Dial, made so as to Enclose a Fragment of such an Instrument brought from Phenicia.—A. Laussedat.—In the year 1866, a portion of the French army was sent to Syria, and, while there, M. Renan obtained, from the commander of this expedition, a number of men to assist him in making some explorations in and near a locality now known as Oum-el-Awamid (the ancient Phenician name of this locality, a few miles to the south of Tyre (Gour), is unknown). While engaged in digging about, a stone was found bearing inscriptions, and, moreover, seen to be a portion of a peculiarly-constructed sun-dial. The author of this paper describes, at great length, this instrument, which, in its restored form, is illustrated by a woodcut.

New Observations on the Variations of the Magnetic Needle.—M. Brown.—A series of tabulated results on the declination of the needle.

Mechanical Equivalent of Heat; and on the Electro-Thermic Properties of Aluminium.—J. Ville.

Researches on the Bromated Derivatives of Anhydrous Acetic Acid.—H. Gal.—The author has poured over fused acetate of soda, monobromated bromide of acetyl, $(C_2H_3BrO_2)_2$. The mixture, having been distilled, yielded a liquid which, after having been rectified, boiled at 245° , and was, on analysis, found to contain, in 100 parts—Carbon, 18.4; hydrogen, 1.5; bromine, 61.5. Formula, $(C_2H_3BrO_2)_2$; that is to say, dibromated anhydrous acetic acid.

Volumetric Estimation of Soluble Fluorides.—P. Guyot.—Since, according to Dr. Nickles, the fluoride of potassium yields, with perchloride of iron, a white precipitate, $Fe_2Cl_2 \cdot 2KFl$, the author has based upon this observation a process of volumetric estimation of the soluble fluorides. He employs standard solutions of known strength, which are not, however, specifically described as regards their preparation.

Fatty Matters contained in the Chyle of Herbivorous Animals.—Dr. Dobroslavine.—Among the fatty substances discovered by the author, is a mixture of stearic and palmitic acids, oleine, and a fat containing a small quantity of nitrogen.

Note on the Calcareous Rock containing the Terebratula Diphyia in the French Alps from Grenoble to the Mediterranean.—Dr. Dieulafoy.

Chemical Examination of a Piece of Cement Metamorphosed while Immersed in the Water of Bayen de Luchon.—F. Garrigou.—In the year 1852, a piece of cement (in all likelihood, an hydraulic cement, since some of it was used to line the cavities of the rock through which the water of the above-named spring runs), of the size of two fists, was placed in a reservoir constantly filled with the warm (64°) water of the spring alluded to. The original cement contained a large proportion of carbonate of lime. The metamorphosed material was found to have taken up a large quantity of silica, some fluorine, and organic matter.

Contemporaneousness of Man, with the Large Ursus Spelæus, and the Reindeer in the Caverns of Gargas (Haute Pyrénées).—F. Garrigou and De Chasteigner.

Application of Thin Sheet-Lead, instead of Lint, in Wounds.—Dr. Burgræve.—The author states that lead feels soft and cool to the wounded parts; its use entirely supersedes that of lint. The formation of a very thin layer of sulphuret impedes putrefaction and the development of small organisms. When once the wound has been dressed with lead, it may be washed as often as desired with water, without the necessity of removal of the dressing. Lastly, the use of lead renders summary operations frequently unnecessary.

Preparation of Aluminium-Ethyl.—Dr. Cossa, in a very short letter to M. H. Sainte-Claire Deville, says that, according to his researches, aluminium acts, at the ordinary temperature, upon iodide of ethyl enclosed in sealed tubes. Aluminium-ethyl was also prepared by the author by causing aluminium to act upon stannethyl.

ence is not yet well ascertained, it is desired that a collection be made of all the observations made on the eclipses of Jupiter's first satellite which are recorded in and disseminated through different periodicals, and also that, from these data, a new determination of the constant value of aberration be made. A new series of researches on the influence which the different colours of the spectrum have upon the so-called respiration of the green parts of plants. New series of investigations and researches to be made of the organic bases contained in the genus *Cinchona*. The Society's gold medal, and, in addition thereto, a premium of £25, will be given to him who finds, either by means of kites or captive balloons, the means of elevating, to great height in the sky, meteorological instruments, so that they may be kept in that position for at least twenty-four hours. The Society's gold medal will be granted for the production of any self-acting and accurately self-registering meteorological instrument—thermometer, barometer, hygrometer—suitable to be fixed to a kite or a captive air balloon for at least twenty-four hours, and so constructed (viz., the instruments) as to give satisfactorily the results of the state of the atmosphere at great height. The two questions open for competition to January, 1873, relate to botany and zoology. The Society desires to recommend to the competitors for prizes to omit, in their answers to questions, any matters not directly relating to the proposed question. It is, moreover, desired, that whatever be sent into the Society should be worked out with accuracy, and that every proposition be well defined and demonstrated, and not mixed with vague theories or badly-digested and not well established facts. The memoirs sent in must on no account whatever be written in the handwriting of the authors themselves, as in this case, even were these memoirs worthy of the award of the medal, no award could be made, according to the Society's rules. The envelopes added to the memoirs sent in, and appended thereto by a peculiar mark, and containing the author's name, will, in case no award is granted, be burnt unopened. The memoirs to be sent in for competition may be written in Dutch, French, Latin, English, Italian, or German languages, at the author's option, provided, in the case of the German language, the Italian, and not the peculiar German mode of writing, be used. All such documents, and the envelopes appended thereto, and just alluded to, should be sent, carriage or postage paid, to Dr. E. H. von Baumhauer, the Secretary of the Society, residing at Haarlem, North Holland, Netherlands. The prize offered for a satisfactory memoir or answer to each of the proposed questions is the Society's gold medal, value £12 10s., bearing the author's name and the year of issue; or, if the author desires it, the full money-value of the medal. In some cases, it is left to the umpires of the awards to grant an additional award of the value just mentioned. The competitor to whose memoir a prize shall have been awarded may not, without the express consent and authorisation of the Society, print or publish, either in whole or part, separately or in any periodical, the memoir to which the prize has been awarded.

Zeitschrift für Chemie von Beilstein, No. 11, 1870.

This number contains the following original papers and memoirs:—

The Isomeric Toluolsulpho Acids.—A. Wolkow.—After referring at great length, to the preparation and purification of the compounds, and their separation from each other, the author describes—*a*, or toluol-parasulpho acid, $C_7H_7(HSO_3)_p$, and the potassa-salt of that acid, $C_7H_7(KSO_3)_p + H_2O$, which is obtainable in large six-sided prismatic crystals; the chloranhydride of the toluol-parasulpho acid, $C_7H_7(SO_2Cl)_p$; the amide of toluol-parasulpho acid, $C_7H_7(SO_2NH_2)_p$; paratoluide of toluol-parasulpho acid; meta-nitrotoluol-parasulpho acid and its chloranhydride and amide; paratoluide—

toluol-metasulpho acid; the amide of the toluol-metasulpho acid. All these, and some derivatives thereof, are described at very great length, but so as to render any further useful abstraction impossible.

Conversion of the Primary Normal Butyl-Alcohol into the Secondary Butyl-Alcohol, or Methyl-Ethyl-Carbinol.—Dr. A. Saytzeff.—By heating the iodanhydride of the normal butylic alcohol with an alcoholic solution of caustic potassa, the author obtained butylen, which was combined with HI; the ensuing compound was converted into a corresponding acetic ether, and this into an alcohol which boiled at about 100° . The oxidation of that alcohol yielded methyl-ethyl-keton and acetic acid, while the alcohol was proved to be methyl-ethyl-carbinol. These reactions are represented by—

Formation of Chloride of Carbon, C_2Cl_4 , from Acetic Acid.—H. Hubner and F. C. G. Muller.—After referring to the researches of Dr. Samosadsky, the authors describe, at length, a series of experiments and preparations, from which they infer that acetic acid, when acted upon by the chloride of phosphorus, exchanges its oxygen for chlorine; so that, as a final result of this reaction, the chloride of carbon is obtained.

Composition of Sugar-Cane.—O. Popp.—The author has analysed fresh sugar-cane, after pulling the leaves off. Martinique and Guadeloupe cane (America) contains, in 100 parts—Water, 72.22; cane sugar, all crystallisable, 17.80; glucose, 0.28; cellulose, 9.30; salts, 0.40. African canes: Middle Egypt (Cairo) contains, in 100 parts—Water, 22.15; cane sugar, 16.0; glucose, 2.3; cellulose, 9.2; salts, 0.35. Upper Egypt—Water, 27.13; cane sugar, 18.1; glucose, 0.25; cellulose, 9.1; salts, 0.42. The author adds, that the quantity of sugar above

Programme de la Société Hollandaise des Sciences de Haarlem, Année 1870.

On the 21st of May last, the general yearly meeting of this scientific Society was held at Haarlem. The Huyghens medal (see *CHEMICAL NEWS*, vol. xx., p. 57) has been granted to M. Rudolf Julius Emanuel Clausius, Professor of the University of Bonn, as principal founder of the dynamic theory of heat. Dr. A. W. H. Kolbe, of Leipzig University, was elected foreign member of this Society. Among the questions open for competition, and to be answered on or before the 1st of January, 1872, we notice the following:—The mode of origin and the part wax plays in living plants; to be investigated by anatomical and micro-chemical researches. To elucidate, by original research, the history of the development of certain malformations and excrescences produced upon oak-trees by various gallicolous *Hymenopterous* insects; it is desired that, in this investigation, the influence of the insect in its successive phases of development, as well as the morphological, anatomical, and chemical changes the part of the plant affected undergoes, shall be duly taken into consideration. Critico-historical exposition of the discovery and development of spectrum analysis, and its applications to chemistry and astronomy. The mathematical theory of the induction coil (*bobine*). Since the value of the constant aberration, as deduced by Delambre from the eclipses of Jupiter's first satellite, differs from the aberration as resulting from later astronomical measurements, and since the cause of that differ-

quoted is an average quantity, since its percentage may reach as high as 20, while the glucose may be entirely absent, and is so in some kinds of cane (different species of the plant), and with good cultivation in all kinds. Sugar-cane dried at 100°, previously deprived of its leaves, yielded from 3.8 to 4.3 per cent of ash; the dried leaves yield by themselves from 8 to 8.5 per cent of ash. The composition of the ash of the American cane, without leaves, is, in 100 parts—Potassa, 7.66; soda, 0.45; lime, 12.53; magnesia, 6.61; oxide of iron, 0.56; silica, 43.75; phosphoric acid, 5.45; sulphuric acid, 16.53; chlorine, 0.21—together, 99.75. Ash of the leaves, in 100 parts—Potassa, 10.65; soda, 3.26; lime, 8.19; magnesia, 2.45; oxide of iron, 0.85; silica, 65.78; phosphoric acid, 1.25; sulphuric acid, 2.13; chlorine, 1.05; carbonic acid, 3.55—together, 99.81.

Qualitative Detection of Sulphurous Acid and Volumetric Estimation of Iron.—O. Popp.—When an acid solution of perchloride of iron is added to a solution of hyposulphite of soda, there is obtained a very deep brownish red colouration, soon passing to amethyst red, and then disappearing, leaving a colourless fluid. The disappearance of the colouration is instantaneous at from 40° to 45°. The author advocates the application of this colouration as a qualitative test for hyposulphites, as well when by themselves as when mixed with sulphates or sulphites. The latter also reduce iron, but without the appearance of the colouration alluded to, which is due to the conversion of the hyposulphurous acid into tetrathionic acid by the action of the acid perchloride of iron. This reaction, which is analogous to the action of iodine upon hyposulphite of soda, takes place according to the formula—

or, rather, because a free acid is to be present; and free tetrathionic acid is formed according to the formula—

The author mentions briefly the volumetric estimation of iron as proposed to be carried on by Dr. A. C. Oudemans, which process is based upon the reaction alluded to; but since we intend to give the paper thereupon in full, we abstain now from quoting the brief description of that process as given here.

Researches on Mesitylen-Sulpho Acids of Mesitylen.—H. Rose.—After referring briefly to Dr. Jacobsen's investigations on this subject, the author treats on the action of bromine upon mesitylen-sulpho-acid, stating that that haloid acts upon the acid, even when care is taken to cool the mixture, most energetically; but, by a circuitous process, the brom-mesitylen-sulpho acid was obtained. In free state, that acid, a solid body, is very soluble in water, alcohol, and ether, from which latter fluid it is most readily obtained in crystals. This substance is very deliquescent, but its salts are difficultly soluble in water. The author describes the baryta, lead, potassa, soda, and copper salt, the formula of the latter being—

The author then treats on the preparation of brom-mesitylen-sulpho acid from monobrom-mesitylen, the body thus obtained, and its salts, being found to be identical with those previously alluded to; researches and experiments on the action of fuming nitric acid upon mesitylen-sulpho acid, and the action of fuming sulphuric acid on the products resulting from the action of nitric acid, are in course of execution.

Glycerine Compounds, and a New Kind of Formation of Allylic Alcohol.—H. Hubner and C. Muller.—The contents of this paper relate chiefly to some rectifications needed in the results of the experiments of Professor Berthelot on this subject, for the authors, while repeating his (Berthelot's) experiments, found very great discrepancies in the results, although exactly carrying out the instructions given by the *savant* alluded to.

Moniteur Scientifique, No. 325, July 1, 1870.

This number does not contain any original memoirs or papers related to chemistry, but we meet here, under the title—

Acoustical Attraction and Repulsion.—J. Guyot.—A reproduction of a paper from a defunct French scientific periodical, here reproduced to show that the experiments Dr. H. Schellbach, in Germany, and Dr. Guthrie, in London, are busy with on this subject were already, to a great extent, made in 1832 by the author.

American Journal of Pharmacy, July, 1870.

This number contains the following original papers and memoirs relating to chemistry, besides several excellent strictly pharmaceutical papers:—

Vaccinine, a Crystalline Principle Extracted from the Leaves of the Cowberry (*Vaccinium vitis-idaea*, L.).—E. Claussen.—The amount of vaccinine in the shrub is about 1 per cent; it forms long acicular crystals, of somewhat bitter taste and devoid of smell. This substance is scarcely soluble in ether, better so in cold water and alcohol, but best of all in boiling water; a saturated solution of this substance in the latter yields, on cooling, a solid mass. When the crystalline substance is heated, it melts to a clear liquid. It is not precipitated by either sub-acetate of lead or tannin, is neutral to test-paper, and contains no nitrogen.

Simple Apparatus for Rapid Evaporisation at Limited Heat, under Reduced Pressure, without the Use of a Pump.—A. B. Prescott.—The author describes, at some length, the use of ordinary

distilling apparatus for the production and maintenance of an approximate vacuum over liquids during their evaporation, in cases where the heat of 120° to 150° F. may be applied.

Report of Professor C. F. Chandler to the Metropolitan (New York) Board of Health, on Various Hair Tonics, Washes, Cosmetics, and other Toilet Ingredients.—The author, by direction of the Board of Health, has investigated the composition of the following articles, viz.:—Hair tonics, washes, and restoratives; lotions for the skin; enamels; and white powders for the skin. Of the substances named in the first category, sixteen were examined, all of which, with but one exception, were found to contain lead, generally in the form of the acetate or sugar of lead. No. 11 among these samples is Mrs. S. A. Allen's "world's hair restorer," of 198 and 200, Greenwich Street, New York. One fluid ounce of this cosmetic (largely advertised) contains—Lead in solution, 5.25 grains; lead in the sediment, 0.31 grains—total, 5.57 grains. The one sample free from lead was an ammoniacal solution of nitrate of silver, containing 4.78 grains of the nitrate in 1 fluid ounce. Of the lotions for the skin (six different samples were analysed), only one was made up with injurious metals—viz., an American compound, known as "Perry's moth and freckle lotion," containing, to the fluid ounce—Corrosive sublimate, 3.61 grains; and crystallised sulphate of zinc, 4.25 grains. Among the enamels for the skin, seven different samples were tested, among which, three containing from 108.94 to 190.99 grains of white-lead in 1 fluid ounce; other samples were found to contain oxide of zinc. The white powders for the skin were found to be chiefly made up of carbonate of lime and magnesia, clay, and French chalk; and as far, therefore, as these materials are concerned, are harmless, except in so far as their application may interfere with the healthy action of the skin.

Ambrosine.—C. U. Sheppard.—With this name is indicated a new fossil resin found in the phosphate bed of South Carolina. The colour of this material is brown; fracture, conchoidal; lustre, resinous; sp. gr., slightly greater than that of water; feebly translucent; becomes strongly electric by friction; melts, at about 460° F., into a clear yellowish liquid; gives off some succinic acid on being heated; is very combustible; is soluble in oil of turpentine, alcohol, ether, and chloroform, also in solution of caustic potassa; and is not decomposed by strong mineral acids.

Archives Néerlandaises des Sciences Exactes et Naturelles, vol. v., parts 1–3, inclusive.

These numbers contain the following original papers and memoirs:—

Temperature of Volatilisation; and on the Specific Heat of Solid and Liquid Bodies.—J. A. Groshans.—This very lengthy essay is an algebraico-physical treatise on this subject.

Simple Method for the Exact and Precise Comparison of Measures of Length.—F. J. Stankart.—This excellent paper, illustrated with several engravings, was originally written and published in Dutch, as far back as the year 1839, but is here reproduced in French at the suggestion of Professor F. Kaiser, partly in order to prove to M. Steinheil, of Munich, that the author (M. Stankart) had, some thirty years ago, already invented what the German *savant* has lately described under the name of *fuhspiegel*, and chiefly because M. Stankart's invention is of the highest importance just now for the purpose of aiding the exact reproduction of the standards of length (*Halon prototype*) of the metre.

Determination of Small Differences of Length, the Measurement of Minute Thicknesses in Small Objects, and the Observation of Very Small Displacements in Large Objects.—F. J. Stankart.—Illustrated with several engravings.

Morphology of the Shoulder-Muscles of Birds.—Emil Senlenka.

Movements of the Eye Illustrated by means of the Phenophthalmotrope.—F. C. Donders.

New Materials to serve for the Knowledge about Cycadææ.—F. A. W. Miquel.

Contributions to our Knowledge of the Flora of Japan.—F. A. Miquel.

Specific Gravity of Alcohol, and of Mixtures of Alcohol and Water.—Dr. E. H. von Baumhauer.—This paper, is written chiefly in order to review the labours of M. D. Mendeleeff* on this subject, and compare the results obtained by him with those the author obtained while exhaustively investigating this subject some ten years ago. The author fully and satisfactorily proves that the strong criticism of M. Mendeleeff against his (Dr. von Baumhauer's) labours on this subject is quite erroneous; and he also, by a new series of very accurately-performed experiments, fully confirms the results before obtained by him. The sp. gr. of absolute and perfectly pure alcohol is, at 15°, equal to 0.7940, water at its greatest density being taken as unit.

New Species of Argostemma: a Contribution to the Flora of the Netherlands' East Indies.—W. F. R. Suringar.

Two New Species of Crustaceæ Living as Parasites on Fishes (Epichthys and Ichthyoxenos).—J. A. Herkots.—With a series of engravings.

Observations on the Character and Formation of Suber and Liber in Dicotyledonous Plants.—N. W. P. Rauwenhoff.

On the Crystallites.—H. Vogelsang.—A crystallo-genetic essay illustrated with engravings.

* Poggendorff's *Annalen*, vol. cxxxviii., pp. 103–141 and 230–279.

Specific Heat of Solid and Liquid Bodies.—J. A. Groshans.—Second essay on this subject.

Place to be Assigned to the Chiromys in the Natural Classification of Animals.—C. K. Hoffmann and H. Weyenbergh, jun.

Results obtained by the Mathematical Study of the Movements of the Eye.—G. F. W. Baehr.

The Petrified Forest of Cairo, the Cliffs of Black Earth and Broken-up Crockery Ware of Lower Egypt, and the First Cataract of the Nile.—H. Hartogh Heys van Zouteveen.

Synthesis of Sulphocyanate of Ammonium.—H. Hartogh Heys van Zouteveen.—When a current of dry ammonia gas is passed through sulphide of carbon at the ordinary temperature of the air, no reaction whatever is stated to take place, according to M. Berthelot, but the author of this paper says—When dry ammonia gas is made to pass through sulphide of carbon, that liquid becomes first yellow, and, after depositing a brick-red coloured substance, becomes colourless again. This deposit, having been separated and dissolved in water, yielded, on partial evaporation of that liquid, some sulphide of carbon and sulphide of ammonium, which volatilised, while a small quantity of sulphur was deposited. The remainder of the solution was found to contain sulphocyanate of ammonium, readily recognised by its behaviour with chloride of iron. The reaction which took place is the following:—

Likewise—

that is to say, first, sulphocarbamate of ammonium was formed, and this was split up, by the heat applied to its aqueous solution, into sulphide of carbon, sulphide of ammonium, and sulphocyanate of ammonium—

Observations on Holtz's Electrical Machine.—V. S. M. van der Willigen.

Volumetric Estimation of Iron by means of Hyposulphite of Soda.—A. C. Oudemans, jun.—This lengthy essay is chiefly written with the view to prove that the critical remarks on the author's former papers on this subject, made by Dr. Mohr, are entirely imaginary. The author has slightly modified his method of operating; but it appears, after all, that, for all practical purposes, his method, as at first described, was found to answer well, as indicated, also, by no less an authority than Dr. Fresenius, not to mention others beside. This paper contains, moreover, the tabulated results of a new series of experiments, which leave nothing to be desired for accuracy.

Observations on Parthenogenesis with Lepidoptera.—H. Weyenbergh, jun.

Origin and Development of the Periphyllus Testudo.—H. C. Ritsema.

Abstract of a Report on the Purification of the Air of Hospitals by means of the Combustion of Organic Germs.—J. van Geuns and E. H. von Baumhauer.—An abstract of a report on M. Woestyn's proposal to purify the vitiated air of hospitals, previous to its exit into the atmosphere, by means of a high temperature (or even red heat), from any organic and organised germs it might happen to contain. The authors point out that M. Woestyn's method, as proposed, is not complete, and not such as to fully carry out the object desired.

Revue Hebdomadaire de Chimie, July 7, 1870.

Manufacture of Carbonate of Baryta and of Artificially-Made Barytic Stones.—M. Allain.—The author employs the native sulphate of baryta of commerce, converts it as usual, first, into sulphuret of barium, and this (by the aid of chloride of zinc) into chloride of barium, and this again (by means of carbonate of soda) into carbonate of baryta. The artificially-made stones consist of a mixture of 2 equivalents of silica, 3 of silicate of alumina, and 10 of carbonate of lime. This mixture having been first ignited, is ground to powder, and there is then added 3 equivalents of powdered carbonate of baryta. This dry mixture is passed through a sieve, and kept in closed vessels free from contact of air. When wanted for use, the mass is mixed with water, and next moulded into the desired shape, yielding, on drying, a very hard, stony material.

Bulletin de la Société d'Encouragement pour l'Industrie Nationale, No. 209, May, 1870.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Report on a Water-Meter Constructed by M. Chameroy fils.—M. Tresca.—The author of this paper, which is illustrated with engravings, speaks in very high terms of the accuracy and efficacy of this piece of machinery, the action of which is based upon an entirely new principle, the maker having succeeded in rendering the flow of the water dependent upon a difference in pressure between the main- and service-pipes, while this value has been rendered effectively invariable. This paper is a valuable contribution to our knowledge about water-meters generally.

Report upon an Annular Kiln, Continuously Working, for Bricks and Pottery.—V. Bois.—This paper, also, is illustrated with engravings, and treats of the construction of a peculiar kind of brick and pottery kiln, the invention of a M. Hoffmann, at Berlin. It appears that this contrivance is suitable, not only for firing bricks, but also for the burning of lime, cement, pottery-ware, and plaster of Paris.

Report on M. Jordan's Work on the Iron Industry.—M. Lamy.—It appears that M. Jordan's published work is one of the most complete hitherto issued on this subject.

Report on the New System of Conveying Beet-Root Juice, according to M. Linard's Proposal.—M. A. Payen.—The author treats of a contrivance whereby the beet-root juice is pressed from the roots, and carried, by cast-iron pipes, to the beet-root sugar-works. The roots are pulped, and the juice expressed, so to say, on the very spot where the roots are grown; and the juice is conveyed, by pipes laid underground (as are gas- and water-pipes) and along the roads, to the beet-root sugar-works, while a portion of these pipes are used in summer time to carry and force up fresh water to the farms.

Cosmos, July 23, 1870.

Coal Formation of the Lofoden Islands (Norway).—S. Meunier.—It appears that, in the Island of Ando, one of the Lofoden group, a seam of coal has been discovered, which, in physical and other properties, bears a resemblance to the well-known boghead, but the thickness of the layer is irregular, and does not, as far as has been ascertained, exceed 20 inches. The diameter of this coal basin is about 2300 metres.

Meteorite of Lodran.—Dr. Tschermak.—This stone contains, in 100 parts—Nickeliferous iron, 32.5; olive, 28.9; bronzite, 31.2; magnetical pyrites, 7.4. The author gives, at length, the separate analysis of each of the enumerated mineralogical constituents.

Unlimited Filtration of River Water.—Dr. Burg.—A lengthy description of an arrangement for filtering the water of rivers, but only, it appears, intended to be applied where no navigation is carried on.

Prevention of Boiler Incrustations.—V. Bois.—The author employs the agglutinated offal of hoofs and horn for this purpose, and states that very satisfactory results have been obtained by the application of this substance, and that even old incrustations are rendered friable, so as to be readily removed.

Revue des Cours Scientifiques de la France et de l'Etranger, July 30, 1870.

This number does not contain any original papers or memoirs directly relating to chemistry or collateral sciences, but it contains—

The Backwardness of Science among the Ancients.—C. von Littrow.—Being his inaugural speech at the University of Vienna. This paper contains several noteworthy facts, among which we mention the following:—The use of the compass in navigation was known to the Chinese in the fourth century; the Arabs made the Europeans acquainted with India in the eighth century, and the crusades of the tenth century brought numbers of Europeans to the eastward, yet the use of the compass was not introduced into Europe until the twelfth century.

Death of M. Daniell Dollfus Ausset.—The town of Mulhouse has just lost a very celebrated citizen, the gentleman just named, brother of the celebrated manufacturer, M. J. Dollfus. The deceased had left the pursuits of industry to devote his time entirely to science, and especially to geology and mineralogy. He was one of the most expert explorers of the alpine glaciers, and his extensive researches in science associate his name with those of Agassiz, Des Desor, and Des Martius. The deceased was a man of great wealth, and was highly respected by all who were acquainted with him.

NOTES AND QUERIES.

Waterproofing.—I shall esteem it a favour if you can inform me of the most approved composition for rendering cloth waterproof; I mean such as is used for tarpaulins of a light colour.—M. A. S.

Carbolic Acid.—"Fitzetienne" would be glad to know of any tolerably accurate method of determining the percentage of carbolic acid in dead oils and other liquids containing small quantities of the acid.

TO CORRESPONDENTS.

* Vol. XXI. OF THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 11s. 10d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxii. commenced on July 1st, and will be complete in twenty-six numbers.

Carbon.—We cannot do better than refer you to our advertisement pages.

J. Wallace Young.—In our next.

A Subscriber.—Messrs. Kent and Co., Paternoster Row, are the publishers.

Arthur E. Davies, Ph.D.—We are obliged for your communication.

J. Cartledge.—The alteration has been made.

Holtman Condy and Co.—Received.

W. H. Wilson.—Forwarded.

THE CHEMICAL NEWS.

VOL. XXII. No. 559.

ON THE COMBINATIONS OF CARBONIC ANHYDRIDE WITH AMMONIA AND WATER.*

By EDWARD DIVERS, M.D., F.C.S.

THE following paper contains an account of some investigations upon the chemical reactions and combinations with each other of carbonic anhydride, ammonia, and water.

The Ammonium Carbonates.

There are certainly three combinations of ammonia and carbonic anhydride, into the formation of which water enters in sufficient relative quantity to allow of their being represented as ammonium-salts of carbonic acid—the normal, the half-acid, and the acid carbonates.

1. *The Normal Carbonate.*—This salt can be prepared by acting on the commercial "carbonate of ammonia" with solution of ammonia. Being only sparingly soluble in the presence of much free ammonia, the normal carbonate is easily obtained in the solid state by using the ammonia in sufficient excess. When the solid commercial salt is treated with strong solution of ammonia, the normal carbonate is left as an indistinctly crystalline, mealy solid; when a concentrated aqueous solution of the commercial carbonate is treated with ammonia gas, the normal salt is thrown down as a crystalline precipitate; when a warm saturated solution of the commercial carbonate in dilute solution of ammonia is set aside, the normal salt is obtained in large crystals; lastly, when a weaker ammoniacal solution of the commercial salt is mixed with alcohol, the normal carbonate is deposited. It can also be formed by allowing a warm concentrated solution of ammonium carbamate in water, or, preferably, in solution of ammonia, to crystallise. But the most interesting way in which it can be prepared is that of treating the same quantity of water a great number of times with fresh quantities of the commercial carbonate at a gentle heat, and allowing the solution to cool and deposit crystals after each addition, when the mother-liquor from the last crop of crystals which forms on cooling will yield large crystals of the normal carbonate on being set aside for some days.

Dalton has given two methods by which he obtained the normal carbonate—one of which was by distilling the commercial carbonate, and collecting the first product of the distillation before it had been exposed to the air; and the other, by adding to a warm saturated solution of the commercial carbonate sufficient ammonia-water to raise the proportion to the proper degree, when, on cooling, it was copiously precipitated. The latter of these methods only succeeds, however, when the ammonia is added in good excess; concerning the former of them, it is to be observed that, when the commercial carbonate is first heated, long fibrous crystals form, but only in small quantity, on the walls of the retort-neck, before the real distillation commences. (Crystals, apparently the same, form on the sides of bottles soon after freshly-made commercial carbonate is stored in them.) These must be the salt which Dalton found (and probably correctly) to be the normal carbonate, as the first product of the real distillation of the commercial salt is, according to the analyses of both H. Rose and the author, not a true carbonate at all.

Ammonium carbonate occurs in the form of elongated plates or flattened prisms. It is intensely ammoniacal in smell and taste. Its composition is expressed by the formula $\text{CO}_2(\text{OH})_2(\text{NH}_3)_2$. Dalton represented it as containing only half this proportion of water, but a comparison of his percentage numbers for it with those he gave for the acid carbonate shows that the salt in his hands really had the composition expressed by the above formula.

Exposed to the air, the crystals are very rapidly destroyed—ammonia escaping, and a wet mass of acid carbonate remaining behind. This change may be expressed as follows:—

At about 58° C., it is converted into water, carbonic anhydride, and ammonia. It is soluble in its own weight of water, or slightly more, at 15°. When boiled, the solution gradually loses the salt, but does not otherwise change in composition. A warm saturated solution exhibits the phenomenon of supersaturation and sudden crystallisation in a well-marked manner, when it is allowed to cool in a closed vessel. The normal carbonate is insoluble in, and is decomposed by, alcohol; it is only very sparingly soluble at low temperatures in solution of ammonia. At a heat of 20°–25°, it is dissolved, with decomposition, in considerable quantity, in strong solution of ammonia, ammonium carbamate being formed. As a means of obtaining crystals of the carbamate, this interesting process for dehydrating the carbonate in solution will be again referred to.

2. *The Half-Acid Ammonium Carbonate.*—Rose obtained this salt by distilling the commercial carbonate very slowly until the contents of the retort liquefied, and leaving the liquid thus obtained to crystallise. H. Sainte-Claire Deville prepared it by crystallising a solution of the commercial carbonate in ammonia-water. It can also be obtained by the action of water on the commercial carbonate—by proceeding as in preparing the normal carbonate—the crops of crystals at length obtained on cooling the warm solutions consisting of the half-acid carbonate. Another method of getting it is to distil the ammonio-magnesian carbonate, the products being a fluid distillate depositing crystals of the half-acid carbonate, and a solid directly condensed, consisting principally, also, of this carbonate. It can also be formed by the action of alcohol on a solution of normal carbonate. It cannot be obtained, although the contrary has been asserted, by cooling a solution of the commercial carbonate to about 0°.

The half-acid carbonate occurs in the form of either thin, elongated, six-sided plates, or flattened right rectangular prisms, terminated by the faces of a rhombic octahedron. The properties of this carbonate appear to be all intermediate to those of the normal and the acid carbonates. The half-acid carbonate has a composition expressed by the formula $(\text{CO}_2)_3(\text{OH})_2(\text{NH}_3)_4$. Rose found it to have another atom of water; but, as he has represented in the same paper some other salts as containing more water than they have been found by other chemists to contain, his results in this case may fairly be questioned. Deville deduced the same composition for this salt from his analyses as that given by Rose, because this was indicated by their mean results. But every sample analysed by him contained adhering water, and one very much more than another; so that it was obviously not right to take the mean results of the analyses as the nearest approach to the true composition of the salt. His analyses indicate, unequivocally, that he examined a half-acid carbonate with much less than five atoms of water—most probably, therefore, with only four atoms of (combined) water, as represented by the above formula.

The half-acid carbonate is soluble in a little more than five times its weight of water at 15°; it is decomposed by less water. The mother-liquor of crystals of the half-acid carbonate is always either neutral, or slightly alkaline, in composition—that is, contains at least two atoms of ammonia to one of carbonic acid.

* Abstract, by the Author, of a paper communicated to the Chemical Society.

3. *The Acid Ammonium Carbonate.*—Unless Rose obtained, as he believed he did, crystals of this salt isomorphous with those of the acid potassium carbonate, it crystallises in only one form, though this may vary very much in the development of its proportions. Rose found the acid carbonate to vary in its degree of hydration, but his results are not in accordance with those obtained by other chemists. At about 60°, it is slowly decomposed into carbonic anhydride, ammonia, and water; on distilling it very slowly, the products of the distillation condense to nearly pure crystalline acid carbonate again. The acid carbonate dissolves in about 8 parts of water at 15°. When some of it is added to a cold saturated solution of itself, it is slowly decomposed, with evolution of bubbles of carbonic anhydride. A warm saturated solution, prepared in a closed vessel under pressure, deposits opaque crystals of it on cooling. A solution of it is converted into a much weaker solution of normal carbonate by boiling it for a time in a flask or retort. The acid carbonate is unaffected by alcohol. Dropped in powder into strong solution of ammonia, it is converted, with the production of a hissing sound and some heat, into a much greater bulk of normal carbonate, which deposits, and a salt which dissolves in the ammonia-water and crystallises out in small quantity on the walls of the vessel, when this is cooled to 0°, soon after the mixture is effected. This salt is probably ammonium carbamate, formed thus—

By digesting the acid carbonate with the strongest solution of ammonia, in a closed vessel at a temperature of 20°–25°, ammonium carbamate is slowly formed in considerable quantity.

The Hyper-Acid Ammonium Carbonate.—Rose obtained this, crystallised from solution, on more than one occasion. He proposed for it the two complex formulæ—

but, as it soon passes into the acid carbonate spontaneously, and is, besides, formed under circumstances which generally bring about the formation of the acid carbonate, it may, with more probability, be regarded as mixed, when obtained with acid carbonate, and represented as having, when pure, the formula—

Constitution of the Carbonates of Ammonium.—The most characteristic reaction of the acid carbonate can only be represented as occurring in the quantity expressed by the formula—

viz., the reaction by which, when warmed with a little water, it passes into carbonic anhydride and the normal carbonate, thus—

The acid carbonate being thus represented, the half-acid one may be regarded as a simple combination of it with the normal carbonate, thus—

The probably tetrabasic character of carbonic acid in many of its salts is recognised by many chemists. The greatest objection to admitting this tetrabasic character seems to be that it shows apparently a dibasic character in a great number of its salts. This difficulty would be removed were the apparently dibasic salts represented as tetrabasic; and facts in the history of many of these carbonates appear to give support to the supposition that in them carbonic acid is actually tetrabasic. This is particularly the case with the carbonates of ammonium. That which is the normal carbonate of dibasic carbonic acid, with an atom of water of crystallisation, becomes a half-saturated salt of the tetrabasic acid; and that which is the acid salt of the dibasic acid becomes an anhydro salt of

the tetrabasic acid, in accordance with its chemical behaviour; while, lastly, the half-acid carbonate of the dibasic acid, with its one atom of water of crystallisation, so oddly associated with the treble molecule of carbonate, becomes a double salt of the other two tetra- or ortho-carbonates, thus:—

Admitting, with Rose, the existence of a hyper-acid carbonate, and adopting for it the formula proposed in this paper, the series of carbonates of ammonium which crystallise from their solutions stands thus:—

The regularity of this series is remarkable, and favours the theory that the half-acid, acid, and hyper-acid carbonates are anhydro compounds of the normal carbonate.

The Normal Ortho-Carbonate of Ammonium.—If the normal meta-carbonate is considered to be an acid ortho-carbonate, a normal ortho-carbonate—that is, a salt having the formula $\text{CO}_4(\text{NH}_4)_4$ —may be supposed to exist. Aqueous spirit converts the commercial carbonate, both solid and in solution, into acid carbonate and a solution more alkaline in composition than the normal meta-carbonate. It acts similarly on a solution of normal meta-carbonate. When water is treated repeatedly with quantities of the commercial carbonate until crops of the half-acid carbonate are obtained, the mother-liquors prove to be more alkaline than the normal carbonate. Dalton mentions having obtained a solution of a “sub-tricar-bonate,” that is, of a salt having three atoms of ammonia to one of carbonic anhydride. Now it seems much less probable that, in these cases, the normal meta-carbonate resolves itself into the acid, or half-acid carbonate, and caustic ammonia, than into one of these salts and the normal ortho-carbonate (or, perhaps, the tri-ammonium ortho-carbonate), thus:—

Besides this, unless the mother-liquor from a crop of half-acid meta-carbonate crystals, which is equivalent to, or even more alkaline than, a solution of normal meta-carbonate, be regarded as containing both half-acid meta-carbonate and normal ortho-carbonate, the half-acid salt must be admitted to be quite insoluble in its own mother-liquor.

Ammonium Carbamate.

Besides mixing the dry gases, distilling ammonium sulphamate with anhydrous sodium carbonate (Rose), and passing dry ammonia and carbonic anhydride into absolute alcohol (Kolbe and Basaroff), there are several other ways by which the carbamate can be prepared. By passing carbonic anhydride and ammonia into concentrated aqueous solution of ammonia, the carbamate can be plentifully formed in crystals. By digesting, in a closed vessel, an aqueous solution of ammonia, saturated with the gas at a low temperature, with either the commercial carbonate or any other carbonate of ammonium, at a temperature of 20°–25°, for thirty-six or forty hours, the carbamate is formed, and either crystallises out at once on cooling, or will do so after cooling the solution in ice, charging it afresh with ammonia, adding more carbonate, repeating the digestion as before, and then again cooling. The commercial carbonate yields the most carbamate, as might be expected.

By heating the commercial carbonate with anhydrous potassium carbonate in a retort, the carbamate condenses

in the neck of the retort as a translucent, crystalline incrustation. The same result is arrived at when, instead of potassium carbonate, anhydrous calcium chloride is used. By distilling, extremely slowly, the commercial carbonate by itself, the parts of the product formed farthest from the heat consist almost entirely of carbamate. The product of distilling the normal carbonate by a heat of 60° is nearly pure carbamate. The distillation of the commercial carbonate with strong aqueous spirit also yields an impure carbamate.

Ammonium carbamate occurs in the form of flocculi; of an incrustation more or less crystalline; of prisms found sometimes projecting from this incrustation; of crystalline laminae (Kolbe and Basaroff); and of well-marked, handsome crystals, neither tabular nor decidedly columnar. Exposed to the air, the carbamate evolves an odour of ammonia, deliquesces, and gradually volatilises almost entirely, the residue being acid carbonate. Although it has a strong physical attraction for water, it only slowly combines chemically with it, especially in the presence of ammonia. Thus, though it deliquesces, very little carbonate must be formed, because so little acid carbonate remains as a residue. Again, it can be obtained in crystals by the union of ammonia and carbonic anhydride in water; it can be dissolved in ammonia-water, and crystallised out again; it can be formed by the dehydration of the carbonate in the presence of water; and it can be a product of distillation along with water. It dissolves, with the sensible production of cold, in about 14 parts of water; it dissolves unchanged, but soon passes into carbonate; it dissolves in a little more than 2 parts of strong solution of ammonia at 15° . From this solution, it can at first be crystallised out by cold, but after awhile the carbonate crystallises out at ordinary temperatures.

(To be continued.)

DESCRIPTION OF DR. C. SCHIEBLER'S CALCIMETER,

OR APPARATUS FOR THE QUANTITATIVE ESTIMATION OF
THE CARBONATE OF LIME IN BONE-BLACK BY
VOLUMETRICAL ASSAY.

THIS apparatus is adapted for the estimation of the quantity of carbonic acid contained in native carbonates, as well as in artificial products, and has been specially contrived for the purpose of readily estimating the quantity of carbonic acid contained in bone-black. The principle upon which the apparatus is founded is simply this:—That the quantity of carbonic acid contained in carbonate of lime can, according to well-known stoichiometrical rules, be used as a measure of the quantity of that salt itself; and instead of determining, as has been usually the case, the quantity of carbonic acid by weight, this apparatus admits of its estimation by volume, and it is by this means possible to perform, in a few minutes, operations which would otherwise take hours to accomplish, while, moreover, the operator need scarcely possess any knowledge of chemistry. The analytical results obtained by means of this apparatus are very correct, provided care be taken to use all the needful precautions.

The apparatus is shown in the annexed woodcut, and consists of the following parts:—(1.) The glass vessel, A, serves for the decomposition of the material to be tested for carbonic acid, which, for that purpose, is treated with dilute hydrochloric acid; this acid is contained, previous to the beginning of the experiment, in the gutta-percha vessel, s. The glass stopper of A is perforated, and through it firmly passes a glass tube, to which is fastened the india-rubber tube, r, by means of which communication is opened with B, a three-necked tubulated bottle. The central neck of this bottle contains a glass tube, v, firmly fixed, which is in communication, on the one hand, with

A, by means of the flexible india-rubber tube already alluded to, and, on the other hand, *inside* of B, with a very thin india-rubber bladder (similar, as regards thinness, to the very light and well-known inflated india-rubber balloons sold as toys). The neck, q, of the vessel B is shut off during the experiment by means of a piece of india-rubber tubing, kept firmly closed with a spring clamp; the only use of this neck of the bottle, B, arranged as described, is to give access of atmospheric air to the interior of the bottle, if required. The other opening is in communication with the measuring apparatus, C, a very accurate cylindrical glass tube, of 150 c.c. capacity, divided into 0.5 c.c.; the lower portion of this tube C is in communication with the tube D, serving the purpose of controlling the pressure of the gas; the lower part of this tube D ends in a glass tube of smaller diameter, to which is fastened the india-rubber tube, p, leading to E, but the communication between these parts of the apparatus is closed, as seen at p, by means of a spring clamp. E is a water reservoir, and on removal of the clamp at p, the water contained in C and D runs off towards E; when it is desired to force the water contained in E into C and D, this can be readily done by blowing with the mouth into V, and opening the clamp at p.

The following apparatus are also supplied with the instrument:—A small and very accurately made weight for weighing off the substances to be tested; a thermometer; a bottle with hydrochloric acid; a bottle containing a solution of carbonate of ammonia; several small porcelain basins; and a book of description, with tables for facilitating the calculations.

The main portion of the apparatus above described, with the exception, however, of the vessel A, is properly fixed by means of brass fittings to a wooden board, as represented in the woodcut. The filling of the apparatus with water is very readily effected by pouring it through a suitable funnel placed in the open end of the tube D, care being taken to remove, or at least to unfasten, the spring clamp at p; in this manner the water runs into E, which should be almost entirely filled. Distilled water is preferable for this purpose, especially as the filling only requires to be done once, because the water always remains in E as long as the apparatus is intended to be kept ready for use. When it is required to fill the tubes C and D with water, so as to reach the zero of the scale of the instrument, it is best to remove the glass stopper from A. The spring clamp at p is next unfastened, and air is then blown by means of the mouth into the tube V, which communicates with E; by this operation the water rises up into the tubes C and D, which thus become filled with that liquid to the same height. Care should be taken not to force the water up above the zero of the scale at C, and especial care should be taken against forcing so much of the fluid up that it would run over into the tube E, and thence find its way to B, whereby a total disconnection of all the parts of the apparatus would become necessary. If by any accident the water should have been forced up above the zero at C, before the operator had closed the spring clamp at p, this is easily remedied by gently opening that clamp, whereby room is given for the water to run off to E in such quantity as may be required to adjust the level of that fluid in C precisely with the zero of the scale. The filling of the tube C with water has the effect of forcing the air previously contained in that tube into B, where it causes the compression of the very thin india-rubber ball placed within B; if it should happen that this india-rubber ball has not become sufficiently compressed and flattened, it is necessary to unfasten the spring clamp at q, and to cautiously blow air into B, through the tube, q, by which operation the complete exhaustion of the india-rubber bladder placed within B is readily performed. This operation is also required only once, because during the subsequent experiments the india-rubber bladder, K, is emptied spontaneously. It may happen, however, that while the filling of the tubes D and C with water is being proceeded with, the india-rubber bladder, K, has become

fully exhausted of air before the water in c reaches the zero of the scale; in that case the level of the water in the tubes d and c will not be the same, but will be higher in d; it is evident, however, that this slight defect can be at once remedied by momentarily unfastening the spring clamp at g.

The apparatus should be placed so as to be out of reach of direct sunlight, and should also be protected against artificial heat, and all sources of heat which might give rise to sudden changes of temperature; the instrument is best placed near a north window, so as to afford sufficient light for reading off the height of the water in the tubes.

The following reagents are required for use with this apparatus:—

Hydrochloric Acid.—The acid required for the decomposition of the bone-black is poured into the vessel s

poured over the salt the mixture of water and ammonia, and the solution of the salt promoted by frequent shaking of the bottle. The solution of carbonate of ammonia is used for the purpose of converting into carbonate of lime any caustic lime which might be present in the materials to be submitted to analysis.

Method of Testing Bone-Black for the Quantity of Carbonic Acid it Contains.

Preliminary Operations.—It is of the greatest importance that a good average sample, really representing the entire bulk of charcoal, be taken for investigation; this can be readily obtained by taking, say, from the filter (in sugar works) or from a cask, small samples, say a few ounces, at various depths of the vessels containing the material; or, better still, if there be room, the charcoal should be placed in a heap on a large sheet of stout canvass, and well mixed together, and samples taken from various spots of the heap. These, if wet (as will be the case with charcoal just removed from the filters), should be dried by suitable means, and afterwards the whole sample should be coarsely ground and thoroughly mixed, and a portion thereof taken for the purpose of being ground up to a very finely divided powder, to serve the purpose of weighing a sample from. It is essential that the charcoal should be ground to a very fine powder, because it greatly promotes the decomposition in the apparatus by the acid.

Weighing off of the Sample for Analysis.—We have seen that there is added to the apparatus a metallic weight to serve as normal weight. This weight is placed in one of the pans of balance (when no balance is at hand purposely made for chemical weighing, any balance, provided it be sensitive to from 1-8th to 1-10th of a grain, will answer the purpose); in the other pan a small porcelain basin is placed, and equilibrium is restored by means of small lead shot. As soon as the equilibrium is restored, the normal, or standard, weight is removed from the pan of the balance, and there is placed in the small porcelain capsule and added to the pan as much of the sample of bone-black to be tested as is required to restore the equilibrium. When several experiments have to be made consecutively, it is better to arrange beforehand the joint tare weight of the normal weight, and of a watch glass of suitable size, and to weigh off upon the latter the several samples. The author recommends the transference of these weighed quantities to a porcelain capsule, because, according to his plan, the samples, after having been weighed, have to be thoroughly moistened with the solution of carbonate of ammonia already referred to, in order to convert any caustic lime which might happen to be present in the material into carbonate of lime; but we think it is a decided improvement to moisten gently with the aforesaid solution of carbonate of ammonia a sufficient quantity of the samples to be tested previous to weighing them; to dry these, as also directed by Dr. Schiebler, and to apply at last, for a few moments, a stronger heat short of red heat (say an air or fusible metal bath, heated to 240° C.), so as to obviate the chance of either an excess of carbonate of ammonia or of water being present, while, at the same time, the decomposition of the carbonate of lime is guarded against.

After the samples are quite cold, they are to be transferred to the flask or bottle A. The author states that more recent researches have proved that bone-black which has been once used for filtering purposes in sugar works no longer contains any caustic lime, and the treatment with carbonate of ammonia can therefore be dispensed with in that case, and need only be employed with samples freshly made.

The experiment for the quantitative estimation of the carbonic acid is carried out in the following manner:—First the water in the tube c is made to stand exactly at the zero (o) of the scale; next the weighed sample of the bone-black to be tested is transferred with great care and without loss, to the bottom of the bottle, A, which should be perfectly dry inside and quite clean. This having been

for use during experiments. This acid need not be pure; the crude acid of commerce answers the purpose, provided it be so diluted that its specific gravity at 17° C. is 1.120. It is not even necessary to adhere rigorously to this strength, and for all purposes here required, it is sufficient to mix two parts by bulk of water with one part by bulk of the commercial hydrochloric acid.

Carbonate of Ammonia.—In order to prepare the solution of this salt of the necessary strength, one part by weight of the ordinary carbonate of ammonia of the shops is dissolved in four parts of water, to which one part of liquid ammonia has been added. The salt is first coarsely pulverised, and immediately after placed in a bottle provided with a well ground-in glass stopper; there is next

done, the gutta-percha vessel, *s*, which should also be previously well cleaned, is filled with the hydrochloric acid above referred to, to within from $\frac{1}{4}$ to $\frac{1}{2}$ inch from the top, care being taken not to drop any hydrochloric acid on the outside of that vessel; this gutta-percha vessel is next placed within the bottle *A* in a slanting direction, as shown in the woodcut; after this the glass stopper is replaced on *A*, care being taken to slightly grease it and the inside of the neck of *A*, thereby securing a better air-tight fitting. The closing of *A* will (if all parts of the apparatus are properly tight) have the effect of slightly lowering the level of the water in *c*, below the zero of the scale, while the water will rise just as much higher in *d*; by unfastening, for a moment, the spring clamp at *g*, the normal height is properly restored. The operator should very carefully guard against handling or touching *A* after it has been once closed, because, by so doing, the warmth of his hand will cause the expansion of the air in *A*, and thereby affect the proper action of the apparatus. In order to cause the hydrochloric acid contained in the gutta-percha vessel placed inside *A* to run on to the animal charcoal, placed on the bottom of *A*, as described, the flask or bottle *A* is taken hold of by the neck, as delineated in the woodcut. As soon as the acid comes into contact with the bone-black, the evolution of carbonic acid gas begins, and with it also the expansion of the very thin india-rubber bladder, *k*, while the water in the tube *c* sinks, and correspondingly rises in *d*. While the bottle *A* is held in the right hand, as already indicated, and gently moved about so as to promote, as much as possible, the contact between the acid and the charcoal, the left hand is employed to gently open the spring clamp, *p*, in such a manner as to run off towards *e* just as much water as is required to keep the level in the tubes *c* and *d* at the same height; both these manipulations should be continued as long as any sinking of the level of the water in *c* is perceptible; in other other words, as long as any carbonic acid is given off. After this has quite ceased, and no change is perceptible, or any motion of the water in the tubes, just alluded to, has taken place, the operation may be considered at an end, care being taken, however, to keep the levels in the tubes *c* and *d* at precisely the same height. This having been done, the next step is to read off the height of the water at the scale on *c*, and simultaneously the thermometer.

EXPERIMENTS ON BUNSEN'S FILTER PUMP.*

By ROBERT H. RICHARDS, M.E.

In the summer of 1869 I was asked by Professor Storer to put up Bunsen's filter pump for the laboratory of the school. In complying with his wishes I have been led to try a number of experiments upon the most efficient form of pump, and have arrived at some conclusions which seem to be worth recording.

It is evident, *a priori*, that an even flow of air and water is necessary, in order to obtain the best results, otherwise the tension of the air inside the partially exhausted vessel will not be constant. The bubbles of air should be round rather than elongated, should be uniformly distributed throughout the entire length of the column of water, and of no smaller diameter than the pipe itself, for if the bubbles are of less diameter than the pipe they will continually flow upwards through the water, and thus a portion of the useful effect of the water would be lost; and if the bubbles are much longer than the diameter of the tube, the vertical column of falling water may be much diminished in length.

In each of the figures (Figs. 1, 2, 3, 4, 5), *a* represents the air-tube, or the tube through which the air is drawn

into the pump; and *f* represents the tube through which the water is fed to the pump.

In the pump described by Bunsen, Fig. 1 (CHEMICAL NEWS, vol. xix., p. 160), I find no small difficulty in adjusting the end of the tube, *p*, so that the above conditions may be fulfilled. I have worked with four different pumps of this pattern, but have never obtained a completely satisfactory result for all rates of speed of flow. At times, when the rate of flow was small, a bubble or air space as much as a foot long would collect just below the pump.

After experimenting for some time with the form Fig. 1, I tried the form Fig. 2, in which the water flows through a tube of uniform bore throughout its entire length, and the air is drawn in through a small aperture in the side of the tube. By this arrangement the result sought for is attained very fairly, the tube being filled with the desired even mixture of bubbles of air and water. Fig. 3 represents a simpler form of the same apparatus, which affords equally good results, and which now receives preference to other forms in the laboratory of the Institute of Technology.

Some time after I had devised this form of pump, I observed that Sprengel (CHEMICAL NEWS, vol. xvii., p. 85) had previously described a similar tube to be used as an aspirator. It should be observed that Sprengel's aspirator is worked by pressure of a column of water, which has not yet entered the apparatus, while in Bunsen's arrangement the power is derived solely from the column of water which has passed the point at which the air and water mix.

The idea subsequently occurred to me that the bubbles might be delivered more evenly and of uniform size if the air were made to bubble up through water contained in a little reservoir, as in *e*, Fig. 4. I find, in fact, that in passing through the water in the reservoir, *e*, the air naturally breaks up into bubbles of uniform size and shape. The same result may be accomplished just as well by the somewhat simpler arrangement, Fig. 5, in which the enlargement, *e*, is dispensed with, but the position is maintained.

The mode of working of this apparatus is probably as follows:—The feed water tends to flow up the air-tube, *k* (Fig. 5), but is met by the air which is being drawn in by the column of water in the waste-tube and is thus forced back for a moment so that a bubble of air is delivered into *i*; the water then rushes up again towards *k*, and is again forced to retreat so as to allow another bubble of air to pass. A continual oscillation between air and water evidently occurs at this point.

I have made several pumps of the form represented in Fig. 5, of tube varying in size from $\frac{1}{4}$ -inch bore to $\frac{1}{2}$ -inch, taking care that the air-feed and waste-tubes in each one of the several pumps should be, as nearly as possible, of the same, and I find that even the pump of $\frac{1}{4}$ -inch bore will yield bubbles of equal size and equally distributed when the supply of air is checked as would be the case when used to exhaust air from a vessel, or when the air is fed into the pump through a small orifice. In this form of apparatus, Fig. 5, the water has no tendency to flow down the walls of the tube, so as to leave elongated air spaces in the centre.

The great advantage of Figs. 3 and 5, is the ease with which they may be made, a single T-joint forms the whole essential part of the construction, but in Fig. 1 the end of the tube at *p* must be carefully adjusted, otherwise the water cannot be allowed to flow at a very slow rate. Fig. 3 will answer well for pumps $\frac{1}{4}$ -inch in bore or less, but the form Fig. 5 should be used for any pump larger than $\frac{1}{4}$ -inch. Fig. 5 represents the only form of pump which, when of a bore much exceeding $\frac{1}{4}$ -inch, seems to be capable of taking down air in the form of bubbles; hence it is the form to be used, if this principle is ever applied on a manufacturing scale in chemical works, in procuring a vacuum for pumping mines, &c.

* Communicated by the Author.

The following experiments were performed rather with a view to explore the subject than with any definite purpose. My apparatus was faulty, the tubes were of the best glass tubing I could find; but glass tubes are, more or less, conical. The connections were all made of caoutchouc tubing made air-tight with shellac. With the large pump, I think the error in starting and stopping the experiment does not exceed 100 c.c. of water; with the small one the error could not amount to 10 c.c.

In the experiments with the $\frac{1}{4}$ -inch bore pump, up to 15 litres of water were used in an experiment; in experimenting with the $\frac{1}{4}$ -inch pump, up to two litres; with the $\frac{1}{8}$ -inch pump, up to 1200 c.c. In the tables here given the water is used as the standard of comparison, and the other elements are reduced in the right proportion.

The first column in the tables, marked height of water column, represents the measurement of the whole fall of water. The second column represents the height of mercury corresponding to that amount of water. The third column, marked P, shows the height of mercury in the manometer, which, in any experiment, if the air be stopped, the water is capable of counterpoising, when it is flowing through the pump at the rate shown by the corresponding water and time columns. The fourth and fifth columns show respectively the amount of water and air which were collected at the foot of the waste-tube, in the time represented in the sixth column.

Experiment 29 was tried four times, but failed on account of the very small power of the water to carry down air when flowing at that rapid rate.

Carbonate of Ammonia having the various times above for tion of this salt of the corresponding height of mercurial weight of the ordinary c for its ordinates, there will be found is dissolved in four parts of water. By Experiments 4, 5, and liquid ammonia has been added. To defects in the tubing, pulverised, and immediately after be seen in either of the vided with a well ground-in glass.

We see, at once, by these experiments, that the longer the time taken to run a given amount of water, or, in other words, the slower the stream, the more air it is capable of carrying down, and the more it is capable of raising the mercurial column when the air is stopped.

The capacity of the pump might be discussed as follows:—

Let P = the number of pounds on the square inch due to H = the total fall of water.

Let r = the ratio of the volume of water in the tube at any time to the whole volume of the tube.

Let h = the useful fall of water.

Then $h = Hr$, and $P = H \times \frac{14.7}{32}$ (for every vertical foot

of water represents $\frac{14.7}{32}$ lbs. of pressure per square inch), but P is never realised, for we never have H, height of water, but Hr; hence, without considering other losses,

the power = $p = Hr \frac{14.7}{32}$ lbs. per square inch; and since r appears in the numerator it is evident, that other things being equal, the more water and the less air the more will be the tension. Loss of power is also due to the retarding influence of friction, f, upon the falling stream, and also is due to the flow of the feed stream. Suppose

the air is allowed free passage, and, under these circumstances, if the velocity in the waste-pipe = 20 feet per second, and that in the feed-pipe = 18 feet per second, we should have a difference = 2 feet per second, which is all that is useful in pulling down air, and which 2 feet per second is due to a fall of only about an inch; by allowing the above rate of speed we should reduce our effective head to 1 inch = h .

Let v = useful velocity.

Let v_1 = velocity of waste.

Let v_2 = velocity of feed.

Then $v = v_1 - v_2$,

or the smaller v_2 is and the larger v_1 the greater will v be; hence, the greatest exhaustion is obtained by turning the feed water off entirely, provided the waste-pipe is full, and, as a rule, the slower the rate of flow the more power due to this cause.

To collect our data we have:—

- No. 1. The more water and less air in the waste-tube the more tension.
- No. 2. Friction increases with velocity of flow; hence, the slower the stream the more the power.
- No. 3. The slower the rate of speed of feed-water the more power. (This follows from 2).

No. 1 may be seen practically in a moment at the pump; thus the water is turned on, and as soon as the waste-pipe is filled with bubbles of air and water the air opening is stopped, the manometer at once begins to rise, and continues to do so until no more bubbles are seen in the waste-tube, when the manometer will stand still and give the maximum exhaustion due to the head, with the rate of speed used.

No. 2 can also be seen in a moment, for the feed can be turned on fast enough to stop all air from coming in when the air has free admission, and, in fact, to force the water back up the air-tube, which would not be true to the laws of falling bodies if it were not for friction.

No. 3 is exemplified thus:—In experiment under No. 1, when the waste-pipe has no air bubbles in it, and is being steadily fed with water, the speed of the feed-water is suddenly increased; the manometer will go down a little if, on the other hand, the feed is partially cut off or its speed checked; a few air bubbles will go down the waste-tube and the manometer will rise; the manometer will be found at its maximum when the waste-pipe is full of water and the feed is entirely cut off.

Next, it is evident that these results conflict with each other, or that there is some point at which a maximum effect can be obtained, though not quite maximum tension nor volume of air per volume of water.

For instance, look back to Experiment 15. We find 1000 c.c. of water carried down 1286 c.c. of air in 1 min. 25 secs. Also look at Experiment 13, 1000 c.c. of water carried down 3402 c.c. of air, but took 5 min. 52 secs. to do it. I think we should find the rate of speed used in Experiment 15 very much more advantageous than that in 13, for the former would carry down very much more air per minute and with very slightly decreased power, as shown by column P.

I have not yet had time to try similar experiments with the form Fig. 1. Very probably the difference between two pumps, one of which delivers its air evenly while the other does not do so, may be small and in fact may, perhaps, be hard to discern in the practical use in the laboratory; still we should use the tools which theoretically work the best, provided no fault can be found with them in practice.

When the platinum cone was tried as represented (CHEMICAL NEWS, vol. xix., p. 160), it was found to clog with a very small amount of precipitate; the same cone was punched with a large number of holes $\frac{1}{16}$ of an inch in bore or thereabouts, and the liquor ran through much faster. It was then observed that the precipitate always collected upon that portion of the filter which was in immediate contact with the platinum cone much more than

anywhere else, and, therefore, that the liquor ran through the paper mostly where it was in contact with the platinum, and hence, it seemed probable that the larger the cone the more quickly would the filtration be performed. A cone was then made 1½ inch in slant height, and punched with the same sized holes, and the water was found to run through very much faster than before. I find that this cone for quickness and for safety is much better than any I have tried; it can be put into any common funnel, no matter how imperfect.

I found that when the filter pump was not used, that I could filter much faster with the large cone under my filter than without it, which exactly corroborates Avery's experiments (*American Journal of Pharmacy*, May, 1868, and also the observation of R. Dale, in the *CHEMICAL NEWS*, vol. xx., p. 128).

ON THE ANILINE OR COAL-TAR COLOURS.*

By W. H. PERKIN, F.R.S.

(Continued from p. 66).

Various Aniline, Phenol, and Naphthalin Colours—Application of the Coal-Tar Colours to the Arts.

LAST lecture we considered, among other subjects, magenta and some of its coloured derivatives, as the blues and violets. This evening we commence with some of the green colouring matters which have also been produced from magenta. The first green colouring matter we shall consider is the "aldehyd green," which owes its name to a substance called "aldehyd" being employed in its preparation. I must, therefore, first tell you what aldehyd is.

Aldehyd is a product of the oxidation of alcohol; it is a volatile liquid possessing a very peculiar odour, and was discovered by a chemist named Döbereiner, but analysed by Liebig. It is obtained by treating alcohol with a mixture of bichromate of potassium and sulphuric acid, and was generally prepared in glass retorts, but, now that it is required for colour making, the glass apparatus is replaced by copper or leaden vessels.

Towards the end of 1861, M. Lauth described a reaction by which rosaniline could be made to produce a blue colouring matter; but this product was found to be useless as a dye, on account of its instability. It was produced by the action of aldehyd upon a solution of rosaniline and sulphuric acid. This useless colour was afterwards experimented upon by a dyer named Chirpin, who, after a number of fruitless attempts at fixing it, told his difficulties to a photographic friend, who evidently thought if it was possible to fix a photograph it was possible to fix anything else. He, therefore, advised his confidant to try hyposulphite of sodium. On making this experiment, however, the dyer did not succeed in fixing his blue, but found it converted into a splendid green dye, now known as aldehyd green.

To prepare this colouring matter, a cold solution of magenta, consisting of one part of colouring matter dissolved in a mixture of three parts of sulphuric acid, and one part of water, is employed; about one and a half parts of aldehyd are added by degrees to this solution, and when the whole is mixed it is heated on a water bath, until a drop of the product diffused in water produces a fine blue colouration. It is then poured into a large quantity of boiling water, containing three or four times as much hyposulphite of sodium as the magenta employed. After boiling a short time the product is filtered off from a greyish insoluble residue which forms. The filtrate contains the green. This process being a very simple one, a

* The Cantor lectures, delivered before the Society of Arts.

great number of dyers now prepare the colouring matter as they require it. It may, however, be precipitated by means of tannin or acetate of sodium, collected on filters and drained to a paste, and, if necessary, dried. In both these forms it is found in the market.

The aldehyd green is principally employed in silk dyeing. It is a splendid colour, and very brilliant both by day and artificial light. The chemistry of this green is at present hidden in obscurity, as it is very difficult to obtain in a chemically pure condition. But like the colouring matter previously described, it is undoubtedly the salt of an organic base apparently containing sulphur.

This base is colourless, or nearly so, and becomes changed to the normal colour of aldehyd green upon absorption of carbonic acid.

It will also decompose ammonia salts, combining with the acid and becoming green. I have here a solution containing the colourless base of this green, an ammonia salt and a little free ammonia. If I pour it upon a piece of white blotting-paper it does not stain it, but if I heat it the ammonia salt is decomposed, and we get the green developed with its ordinary intensity.

There is another green of an entirely different nature to the aldehyd green; it is called the iodine green. This colouring matter is always produced, but in variable quantities, in the preparation of the Hofmann violets, from magenta and iodide of ethyl or methyl. Of late, much attention has been directed to this colouring matter, and by making a few alterations in the process for preparing the Hofmann, from forty to fifty per cent of product can now be obtained from the magenta used. The iodine green is much used for cotton and silk dyeing; its colour is bluer than that of aldehyd green, and it is, therefore, more useful, as it yields, with the addition of yellow, a greater variety of green shades.

Iodine green contains an organic base which is not precipitated by alkaline carbonates. With picric acid it forms a difficultly-soluble picrate, and is generally prepared on the Continent as a paste consisting of this colour precipitated with picric acid and drained on a filter. In England it is, however, sold in alcoholic solution. It is a good green by gaslight.

The next green I have to bring before you is a magenta derivative, commercially called "Perkin's green." In its properties it resembles more closely the iodine than the aldehyd green, but differs from this in its solubility, and in being precipitated by solutions of alkaline carbonates, as carbonate of sodium. It is an organic base which is nearly colourless, and is by no means a chemically powerful body. Like the iodine green, it is precipitated by picric acid, forming a picrate which crystallises from alcohol in small prisms with a golden reflection. This colouring matter is principally employed for calico printing, and is now extensively used. Thus you see we have three aniline greens, some useful for one, and some for another purpose, so that the silk and cotton dyer, and the calico-printer, as well as others can be supplied. For fastness these greens are, I think, quite as good as the violets; the aldehyd green, however, I believe, resists light the best.

In the formation of the mauve, or aniline purple, there is always a small quantity of a second colouring matter produced, of a rich crimson colour, similar to that of safflower. Several years ago I examined this substance, and found it to dye silk a remarkably clear colour, but owing to the press of other matters, and the very small quantities in which it could be obtained, I did not give it any further attention. By a new process, however, it can now be produced in somewhat larger quantities, and endeavours are being made to introduce it to the arts, as it produces beautiful tints of pink upon silk and cotton, and, moreover, can be used for printing cotton, silk, and wool processes, to which safflower cannot be applied as it will not bear steaming. This aniline pink or crimson is a beautiful chemical body, crystallising in small prisms, possessing a golden green lustre. It is soluble in alcohol,

and also in water; it produces solutions remarkable for their fluorescence, so much so, that by certain lights they appear as if filled with a precipitate. In colour and fastness it is equal to safflower, and should it be found possible to manufacture it at a moderate price, I should imagine it would entirely supersede that colouring matter, especially as it is not affected by alkaline solutions.

There is a product in the English market supposed to be an aniline colour called "Field's orange," after its discoverer, Mr. Frederick Field. Its properties are those of a nitro-acid, but as its preparation has not been described, of course I cannot tell you anything about it. With alkalies it forms a rich orange-coloured solution, but by the addition of an acid it is precipitated as a pale yellow powder.

Field's orange is a very useful colouring matter, having a great affinity for animal fibres, and is extensively used for wool-dyeing, as it resists the action of light very well.

We now come to a colouring matter of a very indefinite nature. I refer to aniline black. This substance appears to be closely allied to the insoluble part of the black precipitate formed in the manufacture of the mauve. This precipitate, however, always contains oxide of chromium, which cannot exist in the aniline black generally employed, as no chromium compound is used in its preparation, but as copper compounds are used, it may be that aniline black represents the black precipitate with the oxide of chromium replaced by the oxide of copper, or it may even be that in either case the metallic oxide is not an essential part of this black substance.

Aniline black is perfectly insoluble, and has, therefore, to be formed upon the fibre when employed for calico printing. As we shall have to refer to its application to dyeing and printing, I will not make any further remarks upon it just now.

From mauve and magenta, chocolate maroons and browns are prepared, but, as they are of secondary importance as yet, I will only just mention one or two of the methods of preparing them.

One of the processes for preparing chocolate from magenta is by the action of nitrous acid, but care has to be taken to watch the progress of the operation, and to stop it when the required shade has been obtained. Another process consists in heating magenta with hydrochlorate of aniline to a temperature a little above 200° C. The product, when purified, produces a maroon colour. Browns are generally obtained from the residue of magenta making.

All the colouring matters we have considered up to the present time are derivatives of aniline and toluidine, and constitute nearly all the colours of the rainbow.

By the action of nascent hydrogen upon dinitrobenzol, Mr. A. H. Church and myself obtained, in 1857, a crimson colouring matter, which was named nitrosophenylene. I have lately made a few new experiments upon this remarkable body, and find that it has an affinity for pure cotton, dyeing it of a clear cerise colour, considerably less blue in tint than safflower. With very dilute acids, this colouring matter forms a blue solution; with less dilute acid, a crimson colour, and with concentrated sulphuric acid a green colour. It is difficult to judge of the probable utility of this colouring matter, as it is so difficult to obtain in quantity by the present process. I may mention that my new experiments with this substance have caused me to doubt the purity of the product examined by Mr. Church and myself; and this is not remarkable when we consider how few methods of purifying artificial colouring matters were known at the date of our experiments, as well as the small amount of substance at our disposal.

We now turn to a product very different from aniline, though related to it in some respects very closely. On the table you will see a coal-tar product called "phenol," or "carbolic acid." It was discovered, a long time since, by Runge, and afterwards studied by a great number of chemists. It is only, however, during the last few years, that it has been introduced into commerce in a pure con-

dition, thanks to Dr. Crace Calvert, so well known to the Society of Arts.

Phenol or carbolic acid is a splendid crystalline body, possessing many most interesting properties; but I must confine myself to a short account of its coloured derivatives only.

Carbolic acid, when treated with nitric acid, yields a yellow acid, known as picric acid. This substance can be produced from many other bodies besides carbolic acid, and when first employed for dyeing purposes was generally prepared from the resin of the *Xanthorrhoea hastilis*, but now, owing to the cheapness and purity of carbolic acid, I believe it is exclusively used in its manufacture. Picric acid requires care in its preparation, if phenol and strong nitric acid be employed, as the action is very violent. Pure picric acid is of a very pale yellow colour; it is employed principally for silk dyeing, the colour it produces on silk being much darker than that of the acid itself. Picric acid has a very bitter taste, and by some it is said to be a great improvement upon hops, in the manufacture of bitter beer, especially as it has been proposed as a tonic in place of quinine. Picric acid forms beautiful yellow salts, the most interesting being that of potassium. This salt is extremely insoluble in water, and very explosive; it has been proposed as a substitute for gunpowder for charging shells. Picric acid, under the influence of cyanide of potassium, is perfectly decomposed, and changed into a new compound called isopurpuric acid, a substance isomeric with murexide. The potassium salt of this compound is very explosive, and, to avoid danger, it is generally supplied in a moist condition, and mixed with glycerine. It produces a kind of maroon colour upon wool, but I do not think it has been extensively used up to the present.

Runge, when experimenting with the products of the distillation of coal, obtained two compounds, called by him rosolic and brunolic acids, which he regarded as products existing in coal-tar; I think it most probable, however, that these bodies were produced in his process of purification, and did not exist ready formed in coal-tar.

Rosolic acid was afterwards examined by Dr. Hugo Müller, who obtained it from crude carbolate of calcium, which had been exposed to the oxidising action of the air. This process, however, does not yield rosolic acid in quantity, but, in 1861, Kolbe and Schmitt described a method of producing this substance, by heating a mixture of oxalic, carbolic, and sulphuric acids. It is stated, however, that this process was discovered by M. Jules Persoz, in 1859. It is by this method that rosolic acid is now manufactured.

Commercial rosolic acid, commonly called aurine, is a beautiful brittle resinous substance, having a slight green metallic lustre; when pure it may be crystallised, and if pulverised forms a scarlet orange powder. Its solutions are of an orange colour, but change with alkalis to a most magnificent crimson. It has not been found capable of very many applications in dyeing and printing, although it produces very good orange shades, and with magenta it makes a very good scarlet.

The great difficulty in applying rosolic acid to the arts is owing to the easy solubility of its salts in water. It appears to be closely allied to rosaniline, as it has lately been found possible to obtain it from this colouring matter.

When heated with ammonia, in a closed vessel, to 120° or 140° C., rosolic acid permanently changes into a new colouring matter of a crimson shade, called "peonine" or "coralline." It forms beautiful tints upon silk, similar to safflower, provided it is kept slightly alkaline, but if treated with the least quantity of acid the freshness of its colour is destroyed. When heated with aniline this colouring matter undergoes a similar change to magenta, being converted into a blue called azuline. This colouring matter, as well as coralline, was discovered by M. Jules Persoz, and patented by MM. Guinon Marnas and Bonnet in 1862. Azuline, when in the solid state, presents a

coppery coloured surface; it is soluble in alcohol, but difficultly so in water. It is not manufactured now, having been replaced by the more brilliant blues obtained from rosaniline, and described in our last lecture.

We must now turn our attention to another series of coal-tar colours, derived from a beautiful product called naphthalene. You will see it on the table of coal tar products; it is a hydrocarbon containing $C_{10}H_8$, and may be obtained in any quantity. It is remarkable for the readiness with which it sublimes, and, like benzol and toluol, it yields with nitric acid a nitro compound called "nitronaphthalene," a beautifully crystalline body, and this, with iron and acetic acid, yields an organic base called "naphthylamine." This base is solid, and beautifully crystalline, but possesses a very disagreeable odour.

Mr. Church and myself obtained from a salt of "naphthylamine" and a mixture of nitrite of potassium and potash, a beautiful substance crystallising in orange needles with a green lustre. It is called by a rather long name, "azodinaphthylidiamine."

This substance is a feeble organic base, and dissolves in alcohol, forming an orange-coloured solution, which changes to a splendid violet colour upon the addition of hydrochloric acid. It has, however, been found useless as a dye, because the purple colour only exists in the presence of free acid, and the orange-colour of the base itself is liable to turn brown when exposed to the light. It would appear probable, however, that azodinaphthylidiamine may become useful as the starting-point for new colouring matters, as I have lately succeeded in producing from it a very promising crimson substance, possessing a considerable affinity for animal fibres.

A very beautiful yellow colouring matter has been obtained by Dr. Martius from naphthylamine, somewhat similar to picric acid, but of a much more intense colour. It is prepared by treating hydrochlorate of naphthylamine with nitrite of potassium; by this means a substance known as diazonaphthol is obtained; this is then heated with nitric acid, and is transformed into the new yellow, chemically known as dinitronaphthol. This substance is commercially called Manchester yellow. It possesses the properties of an acid. The commercial compound consists of a beautifully-crystalline calcium salt, soluble in water, and dyeing silk or wool a magnificent golden yellow colour.

Owing to an increasing demand for benzoic acid, experiments have lately been made with a view of obtaining it from naphthalene instead of gum benzoin, &c. For this purpose experiments were made with an acid derived from naphthalene, called phthalic acid, which, when carefully heated with lime, is found capable of yielding benzoate of calcium, from which benzoic acid can be prepared. But as in these processes secondary compounds are formed, which interest us this evening, I will briefly describe the process employed for obtaining these various substances.

First of all, naphthalene is heated with a mixture of chlorate of potassium and hydrochloric acid; in this way a mixture of chloronaphthalene and bichloronaphthalene is obtained. These products are then heated with nitric acid, and yield a mixture of phthalic acid, and a substance called the chloride of chloroxynaphthyl. The phthalic acid is converted into the calcium salt, and heated with slaked lime to a temperature of 350° or 370° C., to convert it into a benzoate.

It is, however, the chloride of chloroxynaphthyl which interests us now. This substance, when heated with an alkali, yields the salts of an acid called chloroxynaphthalic acid, which may be obtained in a free state by means of hydrochloric acid. When pure, chloroxynaphthalic acid is a pale yellow crystalline powder, forming beautiful compounds with baryta, zinc, and copper. It dyes wool a scarlet colour. The great interest of this substance consists in its supposed relationship to alizarine, the colouring matter of madder, the only difference in composition of chloroxynaphthalic acid and alizarine being

in the former containing an equivalent of chlorine in place of hydrogen, thus:—

Many endeavours have been made to remove this chlorine, and to put hydrogen in its place, with the hopes of producing alizarine; but, up to the present time, no definite results have been obtained.

I am inclined to think that, although this relationship of composition exists between these bodies, yet that their chemical nature is quite dissimilar. We generally find that chlorinated bodies have similar properties to those from which they are derived or represent. Chloroxynaphthalic acid, however, does not appear to possess properties similar to alizarine. This acid dyes wool readily without a mordant; alizarine only slightly stains it. When boiled with cloth prepared with alumina or iron mordants, it scarcely produces any change, while alizarine yields intense colours.

This process of preparing benzoic and chloroxynaphthalic acids is carried out on the large scale in France, by MM. P. and E. Depouilly, to whom I am indebted for the specimens of these products shown in this lecture. Some of the chloroxynaphthalates are beautifully-coloured salts, and are used as pigments.

Laurent in his researches obtained a body from naphthalene, called carminaphtha. This product is now claiming the attention of manufacturers, and is said to produce very fine shades of colour upon fabrics.

(To be continued.)

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, August 21, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Spectrum of the Solar Atmosphere.—G. Rayet.

Thermo-Chemical Researches on the Sulphurets.—M. Berthelot.—This lengthy memoir is divided into the following sections:—Reactions of alkaline sulphides upon solutions of metallic salts; reactions of acids upon alkaline sulphides; reaction of sulphuretted hydrogen upon divers metallic salts; and reaction of acids upon metallic sulphurets.

Action of Pentachloride and Pentabromide of Phosphorus upon Divers Ethers.—L. Henry.—This memoir is divided into the following chapters:—Glycolate and lactate of ethyl; diethylic malate and tartrate. The author says that, while hydroxyl, (HO), no matter what be its function (be it that of alcohol, acid, or phenol), is readily replaceable, often even at the ordinary temperature, by an atom of chlorine or bromine, under the action of pentachloride or pentabromide of phosphorus. The methoxyl and ethoxyl are not so acted upon. The author's memoir is too lengthy for further useful abstraction, exceeding even the limits usually permitted for publication of papers in this periodical.

Analysis of Nadorite, a New Kind of Mineral from Constantine (Algeria).—F. Pisani.—The author of this paper begins by referring to M. Fajolot's paper on this subject (see CHEMICAL NEWS, vol. xxii., p. 58); and next states that the last-named experimenter has overlooked the presence of chlorine in this mineral. The results of the analysis made by M. Pisani are, in 100 parts:—Oxide of antimony, 37.40; oxide of lead, 27.60; lead, 26.27; chlorine, 9.0. Formula, $(\text{Sb}_2\text{O}_3, \text{PbO}) + \text{PbCl}$. Nadorite is, therefore, a new and rather remarkable mineral, since it is the first instance that chlorine has been found in a native compound containing antimony. Nadorite is accompanied by a lemon-yellow coloured mineral, which turned out to be an antimoniate and hydrated carbonate of lead.

Hygienic Use of Phenic Acid.—Dr. F. C. Calvert.—The contents of this paper are sufficiently well-known, but there is added to it a foot-note from the hand of M. Dumas, who says that phenic acid has been used as disinfectant, on the large scale, since 1865; in the following year, its use was made compulsory wherever any death occurred, and at all funerals. The hygienic use of this substance is, therefore, far longer established in France than in this country, where, according to the author of the paper above alluded to, it has only been introduced since 1867.

Quantity of Pure Nitrogen given off by Organic Nitrogenous Substances.—Dr. F. C. Calvert.—This paper contains the results of some experiments on the action of hypochlorous acid upon animal matters. The quantity of nitrogen present in these substances is:—For gelatine and albumen, 15.7 per cent; calcine, 15.8 per cent; and wool and silk, respectively, 17.7 and 17.6 per cent. The quantity of nitrogen evolved from these substances by the action of hypochlorous acid varies from 5.391 to 7.81 per cent.

Maximum of Temperature at Poitiers on the 24th of July, 1870.—Ch. Contejean.—The author says it very rarely happens that, in this part of France, the temperature exceeds 35° (95° F.) in the shade, and towards the north quarter of the sky; but on the above-named date, the temperature has been, for several hours, 41° (above 106° F.), and during that time the curious phenomenon could be witnessed of a falling of the mercury in the thermometer, if the bulb thereof were touched by the fingers, or placed in the mouth. The sky was quite bright and clear, and the wind N.E. The city of Poitiers (Département de Vienne) is situated at between 46° and 47° N. latitude, and at about 2° W. of Paris.

Rainfall on the French Alps.—V. Raulin.—There are added to this paper a series of tabulated forms exhibiting the results of meteorological observations made at sixteen different localities, varying in height, above sea level, from 2497 to 2123 metres; while, in every single locality, the observations have been carried on for a great number of years. It is curious to learn that, whereas, in the Pyrenees, the annual rain-fall increases with increase of height above sea level, the reverse occurs in the French Alps, where, on the whole, the quantity of rain which falls is less.

Earthquake in Mexico on the 11th of May last.—Dr. Chassin.—The author describes, at great length, a series of earthquakes which have taken place from the 11th to the 19th of May last in the western part of the above-named country. That portion where this phenomenon was most active has, it appears, undergone very curious changes. Lake Chicagua has entirely disappeared, leaving a dry soil, with the fish, alligators, and other aquatic animals on it. In other places, Cayula among the number, a new lake has been suddenly formed; old, deep wells, which were dry years since, have become filled with water again, and other wells have run dry. Trees have been uprooted by thousands, and whole villages have disappeared.

Cotton Respirators.—Dr. Jouglet.—The author, taking the hint thrown out by Professor Tyndall, has been experimenting on the use of cotton respirators, and states that, by their application, the disease known as miner's anæmia, and also the dangers of the effects of lead, copper, and mercury, to those who have to handle these metals, or work in vapours or dust thereof, may be prevented.

Annalen der Chemie und Pharmacie, June, 1870.

This number contains the following original memoirs and papers:—

Carbonic Acid Ether of the Glycolic Acid Ether.—W. Heintz.—This lengthy paper is divided into the following sections:—Carbodi-glycolic acid ether; carbo-glycolic acid ether.

White Cinchona Bark from Payta.—O. Hesse.—The author found that this bark contains, beside paytin, so large a quantity of starch that the bark might be used as a fermentable and distillable alcohol-producing material. The paytin is a new alkaloid, readily soluble in alcohol, ether, benzene, and chloroform; difficultly soluble in water, in potassa solution, and ammonia; it fuses at 156°, combines with acids, forming salts and double salts. The formula of paytin is $\text{C}_{10}\text{H}_{14}\text{N}_2\text{O}$.

On Mono-Bromotoluol; and on the Derivation of Isomeric Amido Bases from a Hydrocarbon.—H. Hubner and O. Wallach.—This paper contains the following divisions:—Crystallised bromotoluol, $\text{C}_7\text{H}_7\text{Br}$; bromo-nitrotoluol, $\text{C}_7\text{H}_5(\text{NO}_2)\text{Br} \cdot \text{CH}_3$; monobromotoluidine, $\text{C}_7\text{H}_6\text{Br} \cdot \text{CH}_2 \cdot \text{NH}_2$; toluidine; sulphate of toluidine; acet-toluidine, $\text{C}_7\text{H}_6 \cdot \text{CH}_3(\text{NH} \cdot \text{C}_2\text{H}_5\text{O})$.

Some Derivatives of Naphthalene which belong to the Chinons.—C. Græbe and E. Ludwig.—This lengthy treatise is divided into the following chapters:—Biamido-naphthol—

trioxynaphthalin (bioxynaphthol)—

Diamido-Benzic Acid.—P. Griess.

Constitution of Amygdalin and Amygdalinic Acid.—H. Schiff.

Isomeric Cresols.—L. Barth.

Direct Conversion of the Butyl-Iodide of Fermentation into the Amin-Basis of Trimethyl-Carbinol; and on the Conversion of the Butylamine of Fermentation into Trimethyl-Carbinol.—E. Linnemann.

Polytechnisches Journal von Dingler, second number for June, 1870.

The first number for this month has not come to hand; it will be quoted hereafter. This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Improved Hair Hygrometer.—MM. Hermann and Pfister.—The description, accompanied by engravings, of an instrument to determine the moisture of the atmosphere.

Estimation of the Pyrometric Value of Siliceous Substances.

—Dr. C. Bischof.—This paper contains a discussion on the quantity of fluxes which render such substances—as, for instance, fire clay, and mixture of quartz-sand and alumina—fusible to such a degree as will prevent their application to blast-furnaces, puddling-ovens, and the like contrivances. The author tests the materials (native clays, sandstones, &c.) by reducing these substances to an impalpable powder, and mixing therewith from one to twenty times their weight of pure pulverised quartz. These mixtures are kneaded, with water, to a stiff paste, and pressed in prismatic shape, and, after air-drying, exposed to the same degree of heat—a temperature higher than the melting-point of wrought-iron.

Amorphous Silica as a means of Fixing Pigments and Dyes.

—Dr. M. Reimann.—The author describes, at some length, a series of experiments made with the view to apply amorphous silica (as obtained by precipitating a solution of so-called water-glass, silicate of soda, or potassa, with an acid, and collecting, washing, and drying the precipitate in the ordinary way) for absorbing the solutions of fuchsine, aniline blue, &c., and to apply the coloured powder so prepared as a pigment for various materials. The author states that glass, first superficially acted upon by hydrofluoric acid, and next mordanted, as is usual for cotton, assumes, when submitted to the processes in use for dyeing fibre, precisely similar colours as that fibre, and that this effect is caused by the amorphous silica contained in the glass and made active by the hydrofluoric acid.

Preparation of Anthracen.—Dr. J. Gessert.—That portion of the distillation of coal-tar commonly called green grease, and used as wagon- and cart-grease, is, according to the author, the material of coal-tar which contains anthracen, and consists chiefly of a heavy oil, naphthaline, and about 20 per cent of anthracen, which, however, is only contained in coal-tar to an amount of from $\frac{1}{4}$ to 1 per cent. This semi-fluid grease is first placed in a centrifugal machine, in order to expel, mechanically, as much as possible of the oil; the residue is heated to 40°, and pressed, preferably between hot plates. The cake thus obtained (crude anthracen, containing 60 per cent of that substance) is purified by boiling with light tar-oil (coal-tar naphtha), or with petroleum naphtha. The pasty mass is again placed in the centrifugal machine, to remove the last traces of heavy oil, and the material next submitted to sublimation. In order to test the green grease for the quantity of anthracen from 5 to 10 grms. of that substance are taken, placed between folds of filtering-paper, and pressed between hot plates; the remainder of the substance is repeatedly boiled with alcohol, washed with cold alcohol upon a filter, and next dried and weighed. The fusion-point of the mass should be, as near as possible, 210°. The author says that sulphide of carbon is not well suited for the purification of anthracen, because that substance is too readily soluble in that fluid. 100 parts of alcohol dissolve 0.9 parts of anthracen; 100 parts of cold benzol dissolve 0.9 parts of anthracen; and 100 parts of sulphide of carbon dissolve 1.7 parts of anthracen.

Paper, and the Raw Materials it is made of.—Dr. H. Grothe.—This paper is a lengthy memoir and review on the treatise written on this subject by M. Z. Orioli, to whom has been awarded the prize of the Société Industrielle de Mulhouse, which Society has published the treatise alluded to.

New Method for the Preparation of Woody Substances into Pulp suitable for Making Paper.—O. Krieg.—Chiefly a review of what has been done in the United Kingdom as regards making paper from straw, esparto grass, wood, and other materials.

Detection of Sulphate of Soda in Carbonate of Soda.—Dr. Hager.—The author states that it has become customary (at least in Germany) to mix, for the retail trade, crystallised sulphate of soda with the ordinary crystallised carbonate. In order to detect this fraud, the author advises to select a few crystals, or small lumps; place these in a basin, or suitable capsule, so that the lumps are about $\frac{1}{4}$ centim. apart, and then to pour on them a solution of from 1 to 2 parts of corrosive sublimate in 100 parts of 80 per cent alcohol. The crystals of carbonate of soda will become coloured reddish brown by this reagent, while the sulphate of soda remains colourless.

Quantity of Carbonic Acid contained in the Air of School-Rooms.—Dr. Breiting.—The author made a series of fourteen experiments, beginning at 7.45 a.m. and continued to 4 p.m., in a room of 251.61 cubic metres capacity and containing sixty-four children. The quantity of carbonic acid contained in the air of that room during these experiments varied from 2.21 to 9.36 per cent, while free open air con-

tains 4-10,000th of that gas; and a quantity of 1 per cent of the same gas present in air is considered injurious to health.

Moniteur Scientifique, No. 327, August 1, 1870.

This number contains the following original papers relating to chemistry and allied sciences:—

New Method of Treating Native Sulphurets, Antimoniurets, Arseniurets of Copper, Lead, Nickel, Silver, and Iron.—Dr. E. Kopp.—The author first alludes to the mineral resources of Italy, which appear to be far greater and of more value than is generally known or suspected. The difficulty of rendering these treasures industrially available is the great scarcity of fuel. Under these conditions, a series of experiments have been made, to ascertain whether it might be possible to apply cheap and readily-accessible chemical reagents, so to act upon the above-named minerals (without simultaneously affecting the gangue) as thereby to render them in a state fit for being readily converted into metals. As reagents available for the purposes alluded to, the author has found common salt, chloride of iron, and hydrochloric acid readily to suit the requirements. Among the practical suggestions found in this paper, is the fact, that the most economical method to extract the small quantity of copper present in previously-burnt pyrites, consists in first exposing the burnt substance for a time to air and moisture, and then to pour over the material a solution of common salt. A small addition of hydrochloric acid is very useful; the copper thus becomes converted into a soluble chloride.

Preparation of Chromic Chloride.—F. Serena.—Instead of preparing this substance by the method described in books on chemistry, the author makes chlorine gas, previous to coming into contact with pure red-hot oxide of chromium, pass through chloroform or sulphide of carbon. By the use of the last-named substance, the reaction is accomplished according to the following formula—

Towards the end of the operation, it is best to withdraw the flask containing the sulphide of carbon, and to continue the current of chlorine gas strongly.

Utilisation of Nitrate of Soda in the Metallurgy of Nickel and Soda.—R. Wagner.—The author describes, at great length, the method of operations of applying nitrate of soda to the purification of a secondary metallurgical product, a matter consisting, in 100 parts, of—Nickel, 25.22; copper, 37.65; iron, 10.58; sulphur, 26.45. This matte was first fused with the salt just named, and next re-melted with a mixture of 15 per cent of its weight of equal parts of nitrate and carbonate of soda, with the result that a metallic alloy was obtained consisting, in 100 parts, of—Nickel, 40.93; copper, 58.64; iron, 0.25; sulphur, 0.18. The lixiviation of the scoria yielded crystallised sulphate of soda. An arseniuret of nickel, containing, in 100 parts—Nickel, 48.20; cobalt, 1.63; bismuth, 2.44; iron, 0.65; copper, 1.93; arsenic, 42.08; sulphur, 3.07. By fusing this mineral with a mixture of 5 per cent of nitrate of soda and 10 per cent of anhydrous carbonate of soda, the author found that almost all the arsenic was eliminated as arsenate, and was mixed with the other impurities in the scoria. The regulus obtained consisted, in 100 parts, of—Nickel, 90.67; copper, 4.05; cobalt, 0.30; arsenic, 0.62; loss, 0.36.

On Vinage.—(The continuation of the paper quoted, with names of authors, in *CHEMICAL NEWS*, vol. xxii., p. 60.) This portion of this very lengthy memoir is divided into the following sections:—The origin of the alcohols employed for the vinage; the object, or aim, of vinage, and the proportion of alcohol added to wine; the advantage and disadvantage of vinage; the modification vinage brings on in the composition of wine; and the answer to the question whether vinage is a fraud which ought to be prohibited, and, if so, by what means is it possible to improve wines and make them fit to be kept without altering their natural goodness or changing their composition.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 11, 1870.

This number contains the following original memoirs and papers:—

Molecular Volume of Chinon.—Dr. A. W. Hofmann.—The author has experimented on the vapour density of chinon, and has found the following results:—

	Theory.	
	$\text{C}_{12}\text{H}_8\text{O}_4$	$\text{C}_6\text{H}_4\text{O}_2$
Weight of gas volume in reference to hydrogen	108.0	54.00
" " " " " air ..	7.5	3.75

The author states that chinon is undoubtedly a monobenzol derivative.

Methyl-Aldehyd.—Dr. A. W. Hofmann.—The contents of this lengthy paper, full of formulae, bear chiefly upon the determination of the vapour density of the solid methyl-aldehyd, by means of some peculiar compounds of the last-named substance with sulphur. There is added to this memoir the following FS:—

Contribution to our Knowledge on the Sulphaldehyd of the Ethyl Series.

Some Observations on the Camphor Group.—W. Schleichsch.—This memoir is divided into the following chapters:—Action of alkalies on camphoric acid anhydride; on a nitrated derivative of camphor; on a derivative of camphor containing sulphur.

Constitution of Silicic and Hydrofluoric Acids in Aqueous Solutions.—J. Thomsen.—The author has experimented thermally

on the phenomena of neutralisation and basicity of the acids above-named, and states—The formula of silica in aqueous solution is that ordinarily accepted, $\text{Si}(\text{OH})_4$; hydrofluoric acid, in aqueous solution, behaves towards silicic acid as a monobasic biatomic acid, having as formula— H.Fi.H ; the normal compound, the product of the reaction of silicic and hydrofluoric acids upon each other is— $\text{Si}(\text{Fi.H})_4$.

New Method of Preparation of Organic Chlor-Bromine Compounds.—L. Henry.—The author describes some experiments to prove the possibility of using chlor-iodethylen and chlor-iodhydride for the purpose of obtaining the organic compounds above-mentioned, but an excess of bromine is necessary for the full reaction.

On Tribromhydride.—L. Henry.—This paper is chiefly a reply to M. Berthelot, who had criticised the author's experiments and researches on this subject.

Contribution to our Knowledge of Crotonic Acids.—A. Kekulé.—This lengthy memoir is chiefly a critical review of the labours of a large number of scientific chemists on this subject, and contains such of the author's researches as may serve to bring about harmony and clear away doubts existing on this subject. The memoir is accompanied by diagrams and a large number of quotations from various scientific periodicals.

Curcume, the Pigment of Turmeric Root.—F. W. Daube.—The author begins by stating that the substance hitherto known as curcume, and usually obtained from the drug known as turmeric, by means of exhausting it with alcohol, is not pure curcume, but a mixture of that body and various resinous matters. The preparation of curcume is described as follows:—The previously coarsely-pulverised drug is submitted to a process of steaming, in order to remove the essential oil. The residue is next washed with boiling-water as long as that fluid becomes coloured; the material is then thoroughly dried, and next exhausted with boiling benzol (this fluid is only a very indifferent solvent for curcume, since 1 part of the latter requires 2000 of the former for solution; but the use of benzol is, after all, indispensable, since it is the only fluid which leaves the resinous matter of the drug undissolved). On cooling, the hot benzol deposits crude curcume, which is further purified, first, by being pressed between folds of blotting-paper, and next being dissolved in alcohol. The alcoholic solution is filtered, in order to separate a small quantity of a yellow-coloured flocculent matter. The filtrate is next precipitated with an alcoholic solution of acetate of lead. The ensuing precipitate is collected on a filter, washed with alcohol, next diffused through water, decomposed by sulphuretted hydrogen, and the mixed sulphide of lead and curcume collected on a filter, washed, dried, and next exhausted with alcohol, which dissolves the curcume. This solution being left to spontaneous evaporation, leaves curcume in crystalline state, as a body, readily soluble in alcohol and ether, also in alkalies; the solution, in that case, exhibiting a bright red-brown colouration. Curcume is insoluble in water; concentrated mineral acids (sulphuric and hydrochloric) dissolve it, but also alter it; it combines with lime and baryta, forming insoluble red-brown coloured compounds; its combination with metals are all insoluble in water; the lead compound is of a brick-red colour. Curcume fuses at 165° , does not sublime, but is decomposed when further heated. The formula of curcume is $\text{C}_{10}\text{H}_{12}\text{O}_6$, and that of its lead compound $\text{C}_{10}\text{H}_{12}\text{PbO}_6$.

Derivatives from Albumen Compounds.—W. Knopp.—This paper contains an as yet imperfect and preliminary notice on the action of sulpho-vinic acid upon albumen.

Derivatives of Hexyl-Hydride (Hexylwasserstoff, C_6H_{14}).—C. Schorlemmer.

Peculiar Formation of Cetyl-Alcohol.—C. Schorlemmer.—When a mixture of sebac acid and caustic baryta are submitted to dry distillation, there is formed, beside other products, a solid body, which, after having been purified, and re-crystallised by means of alcohol, yielded, by elementary organic analysis, results leading to the formula $\text{C}_{18}\text{H}_{38}\text{O}$. The substance in question fuses at 49° , and possesses all the properties of cetyl-alcohol.

On Curcume.—Iwanof-Gajewsky.—This author, who has been investigating this subject simultaneously with, and independently of, the author of a paper on this subject alluded to above, states that sulphide of carbon takes up, from turmeric, an oil containing, beside oxygen, 80.2 per cent of carbon and 10 per cent of hydrogen. This oil boils at from 240° – 250° . The drug having been next treated with ether, yields, to that solvent, curcume, as yellow-coloured crystalline body, $\text{C}_{10}\text{H}_{12}\text{O}_6$, fusing at 172° ; the drug contains, moreover, another pigment and an alkaloid.

Zeitschrift für Chemie von Beilstein, No. 12, 1870.

This number contains the following papers and memoirs:—

Substance Present in Bran which Yields Furfural.—M. Gudkow.—The chief results of the author's researches are:—Furfural is formed by a peculiar material present in bran to an amount of from 15 to 20 per cent, and chiefly contained in the husks of the grain, to which it imparts its elasticity. This furfural-producing matter is insoluble in water, but soluble in very dilute sulphuric acid and in caustic potassa. When boiled with very dilute sulphuric acid, this substance is converted into a peculiar saccharine matter, which, on being treated with stronger sulphuric acid, yields, by distillation, furfural. When cattle are fed with bran, the material which yields furfural passes into their faces. The author quotes a series of results of analysis of bran made by various chemists and at different periods of time; the quantity of woody fibre, recorded in these analyses as present in bran, varies from 4.1 to 34.6 per cent, while the quantity of starch and gum is put down at figures varying from 21.7 to 61.5. From these discrepancies,

coupled with the fact that none of the analysts mention the material which yields furfural, the author concludes that a portion of the quantities recorded as woody fibre, and a portion of that recorded as starch, ought to be quoted as furfural-producing matter—a substance which does not simply occur in bran, but also in oil-cake, madder-root, and other plants.

Four Isomeric Ethyl-Naphthol-Sulpho Acids.—B. Maikopar.—The author describes briefly:—a ethyl-naphthol-sulpho acid,

and its baryta and potassa salt, the former fusing at about 57° and becoming thereby decomposed; the β acid, and the salts it forms with the same bases; and also the γ and δ acids, with some of their salts.

Bromonitro- and Bromamido-Benzol, and on the Position the Hydrogen of Benzol Occupies.—H. Hubner and M. Alsberg.—The authors say that they undertook these researches chiefly with the view of ascertaining whether the position of the 6 atoms of hydrogen contained in benzol is the same. For this purpose they have studied the bromonitrobenzols, of which they describe an α and β compound, the formula of the former being a $\text{C}_6\text{H}_4\text{BrNO}_2$; further, an α and β bromamidobenzol, the former a solid substance, crystalline, fusing at 64.5° ; the latter, formula $\text{C}_6\text{H}_4\text{BrNH}_2$, a fluid which, when submitted to the influence of great cold, becomes solid, and, once solidified, remains solid, even up to 31° . The authors also describe, somewhat categorically, a series of salts, and, as regards the position of the hydrogen atoms of benzol, they come to the conclusion that the position and quantivalence of these atoms is the same for each of them.

On Agoniada and Agonidine.—Dr. P. Peckolt.—The author has extracted from the agonia bark (*Plumeria lancifolia*), a tree indigenous to the Brazil, the bark being largely used in that country as febrifuge, a substance which he calls agonidine, a crystalline matter, devoid of smell, of a very bitter taste, difficultly soluble in ether but more readily so in boiling alcohol and boiling water, does not sublime on being heated, is soluble, also, in solution of caustic potassa; in ammonia and in concentrated sulphuric acid, the latter solution is at first of a golden-yellow colour, but turns gradually green. Upon the addition of nitric acid to the sulphuric acid solution of agonidine, a yellow-coloured flocculent matter is separated; this substance is a glucoside identical with arbutine, and contains no nitrogen. The formula of agonidine is $\text{C}_{10}\text{H}_{11}\text{O}_6$.

NOTES AND QUERIES.

Condensing Hydrochloric Acid Gas.—What time, and space of condenser, is required to condense the HCl gas produced from 856 lbs. ordinary common salt?—SALT.

Waterproofing.—"M. A. S." is referred to Ure's "Dictionary of Arts, &c." vol. iii., and to Cooley's "Cyclopædia of Practical Receipts." Both works may be inspected at the Library of the Commissioners of Patents.

Estimation of Alkalies in Silicates.—Can any of your readers inform me where to find Dr. Lawrence Smith's recent method of estimating the alkalies in silicates? I would suggest that a description of this process will be of value to a great many of your readers.—ANALYST.

Carbolic Acid.—(Reply to "Fitzetienne.")—Since the boiling-point of carbolic (phenic) acid is 188° , it is clear that it will be found in the products distilled over between 150° and 200° . The oily liquid, distilling over at that temperature, should be well mixed with a solution of caustic soda, which combines with the carbolic acid, forming a compound which may be readily decomposed by any strong mineral acid. To be brief, the process comes to a preparation of carbolic acid, carried on so carefully as to render it suitable for ascertaining quantities. For full particulars you are referred to Schützenberger, "Traité des Matières Colorantes," vol. ii., pp. 4, 5.

Brewing Queries.—Can any of your readers supply me with either references or directions for brewing household beer—say 20 gallons at a time. I can manage the malt extremely well; but on each occasion when I have tried sugar, it never fines, or requires several months, and in either case has a sickly taste. The last may, perhaps, arise from using loaf sugar. I may add that I have tried the directions given by Donovan, in his "Domestic Economy," and also by boiling the sugar and hops, and fermenting in the usual way, "setting on" at about 25° – 70° . (1) What are the relative values of malt and sugar? I have been accustomed to boiling down to 25° for the malt, and in sugar-beers calculating the sugar same strength. (2) How can I overcome the disposition of the sugar-beer holding in suspension the albumen, and get it clear and bright in a few days?—T. GREGSON.

Analysis of German Silver.—A good method of separating copper, nickel, and zinc, is to dissolve the alloy in hydrochloric acid containing a few drops of nitric acid, and precipitate the copper from the slightly acid solution in the form of sub-sulphocyanide of copper. The liquid, after being filtered and reduced, by evaporation, to a small bulk, is treated by excess of caustic potash, and then by hydrocyanic acid, until the precipitate which is at first formed is completely re-dissolved with a yellow colour. In this liquid, which contains the double cyanides, the zinc is precipitated in the state of sulphide, by means of protosulphide of potassium (not sulphide of ammonium). After some hours' digestion, and when the precipitate is completely deposited, it is filtered off, and, after boiling the liquid with *aqua regia*, the nickel is precipitated as oxide by caustic potash. This oxide must be calcined after it is dried.—F. WÖHLER.

THE CHEMICAL NEWS.

VOL. XXII. No. 560.

ON THE ALKALINITY OF CARBONATE OF LIME.

By W. SKEY,

Analyst to the Geological Survey of New Zealand.

CARBONATE of lime is described in chemical works as neutral to test-paper, but this scarcely agreeing with the results of observations I have had to make upon this point in the course of other investigations, I beg to give these results, which are as follows.—

1. Carbonate of lime, prepared by igniting pure oxalate of lime in a close crucible, at a dull red-heat, gives an intense alkaline reaction with reddened litmus-paper, after moistening with distilled water, or after re-ignition with pure carbonate of ammonia.

2. Carbonate of lime, prepared directly from chloride of calcium and bicarbonate of soda, by admixture of their aqueous solutions, and washing the ensuing precipitate till all the soda was removed, gave the same reaction with test-paper.

3. Limestone, shells (calcareous), calc-spar crystals, and arragonite, are all strongly alkaline to test-paper (at least, the samples I have tried were), the powder of any of these substances, washed with distilled water for many days, does not seem to lose any of this alkalinity.

Lastly (and, I think, conclusively), precipitated carbonate of lime, prepared by either of the above processes, when agitated with weak hydrochloric acid, in successive quantities, until gradually reduced to a minute proportion of its original bulk, still manifests this reaction to an eminent degree; indeed, the solution could not be rendered permanently acid till the whole of the carbonate was dissolved.

It seems impossible, under these circumstances, to attribute this reaction to the accidental presence of free magnesia or lime, sub-carbonate of lime, or alkaline carbonates, in the precipitate; this reaction may therefore, I think, fairly be attributed to the carbonate of lime.

NOTE ON

SOME NEW DERIVATIVES OF COUMARIN.

By W. H. PERKIN, F.R.S.

In a paper read at the Chemical Society in May last,* I described some new bromine derivatives of coumarin, viz.,—

Dibromide of coumarin	$C_9H_6O_2.Br_2$
Bromo-coumarin	$C_9H_5BrO_2$
Dibromo-coumarin	$C_9H_4Br_2O_2$

and stated that the two latter compounds, when treated with potassic hydrate, yielded the salts of new acids. At that time I thought it possible that these products might be derivatives of coumaric acid. A more extended study of this subject, however, has shown that this is not the case.

When dibromo-coumarin is boiled with aqueous potassic hydrate it rapidly dissolves; the resulting solution, however, becomes, in a short time, a magma of crystals. These consist of the potassium salt of a new acid. Potassic bromide is also formed in large quantities. The reaction may be expressed thus:—

Dibromo-coumarin.

Potassium salt of
new acid.

* CHEMICAL NEWS, vol. xxi., p. 247.

The acid obtained from this potassium salt is crystalline, and possesses a very bitter taste; its formula is—

Bromo-coumarin behaves in a similar manner when heated with potassic hydrate, producing a crystalline salt and potassic bromide. The acid obtained from this has not yet been analysed. It probably possesses the formula

In the preparation of coumarin from hydride of salicyl it will be remembered that the hydride of sodium salicyl is heated with acetic anhydride; by modifying this process, and employing the sodium derivative of bromo-salicyl in place of that of salicyl, I have obtained a new bromo-coumarin differing entirely from that produced by the action of bromine on coumarin. It fuses nearly 50° C. higher, and although soluble in boiling potassic hydrate, is not decomposed by this alkali under ordinary circumstances. We have now, therefore, two monobromo-coumarins.*

Coumarin, when treated with fuming sulphuric acid, dissolves, forming a sulpho-acid, having the formula—

The acid crystallises in brilliant octahedra, which, when removed from their mother-liquor, rapidly become opaque. It forms a beautiful barium salt containing—

When heated strongly with sulphuric acid coumarin gives a disulphoacid, $C_9H_6O_2.2SO_3$.

None of the derivatives of coumarin I have examined appear to have any tendency to unite with water and form derivatives of coumaric acid.

ON THE

COMBINATIONS OF CARBONIC ANHYDRIDE WITH AMMONIA AND WATER.†

By EDWARD DIVERS, M.D., F.C.S.

(Concluded from p. 75.)

AMMONIUM-CARBAMATE heated to 59° or 60° furnishes vapour of the full tension, but it also volatilises at ordinary temperatures. It has a four-volume vapour, and this is the case even at ordinary temperatures, according to Bineau. It is, therefore, decomposed in volatilising into carbonic anhydride and ammonia. Further evidence of this is afforded by the fact that the vapour of carbamate may cool down to a much lower point than that at which it is formed before it condenses.

Rose has pointed out the following reactions of the carbamate as distinguishing it from the carbonates of ammonium:—It is not perceptibly affected by dry hydrochloric acid in the cold, and, warmed in the acid, is decomposed without liberation of water; in dry chlorine it is not affected at first, but is slowly decomposed without liberation of water; it assumes in the cold a pale yellowish colour when placed in sulphurous anhydride; it does not form water when heated in sulphuretted hydrogen, and it yields carbonic anhydride without effervescence when the vapours of sulphuric anhydride are passed over it. Besides these, it has a special reaction in solution with calcium chloride; when mixed with anhydrous calcium chloride, it can be expelled by a gentle heat, leaving the chloride

* Dr. H. Busecke by employing the sodium derivative of the hydride of chlorosalicyl in a similar manner has obtained a chloro-coumarin possessing properties analogous to those of this new bromo-coumarin. *Ann. d. Chem. u. Pharm.*, April, 1870.

† Abstract, by the Author, of a paper communicated to the Chemical Society.

unchanged; it does not melt or become moist when heated; and it dissolves freely in strong ammonia water.

The constitution of the carbamate is almost certainly that indicated by its name, and represented by the formula— $\text{CO}_2(\text{NH}_2)(\text{NH}_4)$. But no metallic carbamates have as yet been obtained. However, by mixing a very concentrated ammoniacal solution of ammonium carbamate with a saturated solution of calcium chloride, a precipitate may be obtained which is soluble in water, though the solution almost immediately deposits chalk. This precipitate proves, on analysis, to be either calcium carbamate or a double carbonate of calcium and ammonium; which of the two cannot be decided because of the presence of water and other impurities. Ammonium carbamate may be represented as an orthocarbamic acid, thus—

but there is no evidence as yet to support this view of its constitution, unless it be that afforded by the fact that ammonia prevents the passage of the carbamate into carbonate, which may be supposed to be due to the union of the ammonia with this acid to form an orthocarbamate slightly more stable, according to this equation—

The "Carbonate of Ammonia" of Commerce.

In the main, the published analyses of this substance show that the samples examined had about the composition expressed by the formula—

Samples of the carbonate at present in commerce, obtained from various sources, have proved to be of very uniform composition (with one special exception); this, however, is not expressed by the above formula, but by the simpler one—

The percentage numbers obtained agree closely with the calculated numbers, except that they indicate the presence of 1 or 2 per cent additional water and a slight excess of ammonia, but to an extent quite immaterial so far as the determination of the atomic composition is concerned.

Several proofs, other than analytical, can be adduced to show that the carbonate now in commerce differs from that most generally in commerce formerly. One is that, as has been already mentioned, ammonium carbamate condenses out of the products obtained by distilling together the carbonate and anhydrous calcium chloride. The following equations show that this can only take place when, of the two carbonates, that now in commerce is employed:—

To form
carbamate.

The single exception observed to the uniformity in composition of the commercial carbonate was the occurrence of a layer of *acid carbonate* adhering to a layer of the usual carbonate. It was crystalline, almost devoid of ammoniacal taste and smell, and was permanent on exposure. An instance of the occurrence of the acid carbonate in commerce was noticed by Phillips fifty years ago. It has already been mentioned that the acid carbonate can readily be obtained in this form by the slow distillation of its ordinary form.

The ordinary commercial carbonate, exposed to the air, loses a proportion of its weight, corresponding to that calculated from the formula now found for it, on the assumption that the carbamate in it volatilises and the acid carbonate remains. It dissolves in 4 parts of water at 15°, so that it and the half-acid carbonate both possess solubilities which seem to directly depend upon the amount of acid carbonate they each contain. A warm saturated

solution cooled, deposits crystals of acid carbonate; the mother-liquor warmed with fresh commercial salt again deposits acid carbonate, and the same thing will occur several times on repeating these operations; at length, the mother-liquor, warmed with fresh commercial carbonate, deposits crystals of the half-acid carbonate, and the same thing also occurs several times on repeating the operations; then the mother-liquor from one of these crops, which is a very concentrated solution and contains to one atom of carbonic anhydride more than two of ammonia, deposits gradually a considerable quantity of large crystals of the normal carbonate; lastly, if, instead of waiting for these crystals to form, the normal carbonate is precipitated by passing a current of ammonia gas through the mother-liquor kept cold, the salt remaining in solution appears by its reaction with calcium chloride to be—at least, a large proportion of it—the ammonium carbamate.

The commercial carbonate heated with anhydrous potassium carbonate evolves large quantities of ammonia at a temperature of 50°–60°; when this evolution has nearly or entirely ceased, and the heat is carried to 65°, carbonic anhydride and ammonia escape in the proportion in which they form carbamate, and acid potassium carbonate remains behind. Two reactions, therefore, occur; firstly, a combination of carbamate with acid potassium carbonate is formed, and then this is decomposed, thus:—

To form
carbamate.

When calcium chloride is used instead of potassium carbonate, the carbamate-forming gases come off below 65°, and this fact, besides that of the volatility of the uncombined carbamate, affords further proof that, when potassium carbonate is used, the carbamate is held in chemical combination with acid potassium carbonate. When the solid hydrated calcium chloride of commerce, which contains about two atoms of water to one of the chloride, is mixed in powder with the commercial carbonate, the mixture has no smell, soon grows warm, swells up, evolves large volumes of carbonic anhydride, and, after gentle heating, consists of chalk and ammonium chloride, together with any excess of either substance used. Regarded as a single substance, the commercial carbonate is best represented as a double salt of carbonic and carbamic acids with ammonium, thus:—

Products of the Distillation of Sal-Ammoniac with Chalk, with Potassium Carbonate, and with Sodium Carbonate.

It is always stated that the products of the distillation of sal-ammoniac and chalk are the substance

water, and free ammonia; but this must be done upon theoretical grounds only. When these substances are distilled together, the vapours evolved entirely condense to water and a slightly hydrated carbamate. The formation of the commercial carbonate takes place during the refining process, which consists, as is well known, in re-distilling the products of the first distillation with a little additional water, at a temperature of about 65°. A mixture of sal-ammoniac with either anhydrous potassium or sodium carbonate also yields, when distilled, water and a slightly hydrated carbamate, but some ammonia escapes in the first stage of the operation. This arises from some of the undecomposed alkaline carbonate fixing carbonic anhydride and water, thus:—

When pearl-ash is distilled with fully its equivalent of

sal-ammoniac and with aqueous alcohol, as in preparing *spiritus ammoniac aromaticus* (Ph. Lond.) the distillate, as has long been known, is a solution of normal carbonate or equivalent in composition to it. But the first and more alcoholic portions, collected separately, soon deposit crystals of the half-acid carbonate, the mother-liquor being left basic or with more than two atoms of ammonia in it to one of carbonic anhydride. By following the directions of the British Pharmacopoeia, and using the commercial carbonate of ammonia and water of ammonia in place of pearl-ash and sal-ammoniac, similar results are obtained.

Products of the Distillation of the Commercial Carbonate of Ammonia, of the three Ammonium Carbonates, and of the Ammonio-Magnesian Carbonate.

When the carbonate of ammonia of commerce is distilled, it is re-obtained as almost the sole product, unless the distillation is carried on exceedingly slowly. In this case some carbamate, mixed with only a little carbonate, is obtained, in the further end of the retort-neck, and also, near the termination of the process, a little of a more hydrated and carbonated product than the commercial carbonate, but the great bulk of the quasi-sublimate is still the commercial carbonate, $(\text{CO}_2)_2\text{OH}_2(\text{NH}_3)_3$.

Rose distilled the carbonate formerly in commerce very slowly, and found some of the remote part of the product to have a composition expressed by the formula

and the bulk of the product to have a composition which is that of the carbonate now in commerce with 5 per cent additional water, though he gave it a formula which would now be written

Products thus obtained are always moist when first formed, so that neither of these need be regarded as a single and definitely hydrated substance. Distilled with alcohol the commercial carbonate yields carbamate and water.

When the normal carbonate of ammonium is distilled very slowly the products are the carbamate and water, and when the acid carbonate is similarly distilled the product is the acid carbonate again; but when either the normal, the acid, or the half-acid carbonate is distilled more rapidly, partial condensation only of the products takes place, and in such a way that the carbonate of commerce is formed, according to the equations—

It has already been mentioned that the half-acid carbonate can be obtained by distilling the ammonio-magnesian carbonate. This, however, is probably a secondary product. The true products appear to be water, carbamate held in solution in the water and rapidly becoming hydrated, and, towards the end of the distillation, some acid carbonate.

The Single or Chemical Substances that are Formed by Condensing Mixtures of Carbonic Anhydride, Ammonia, and Water.

All compounds of carbonic anhydride with ammonia and water are decomposed into these substances when they are heated. The products of their distillation are, therefore, results of these substances combining together.

Ammonium carbamate is one of the single or chemical substances formed from a mixture of carbonic anhydride, ammonia, and water. The conditions for its formation appear to be the presence of the ammonia in the proportion of at least two atoms of ammonia to one of the carbonic anhydride and a little water in the liquid state.

Acid ammonium carbonate is another single substance formed from the above mixture. The condition for its formation appears to be the introduction of water-vapour and ammonia in atomic proportions into carbonic anhydride so slowly that the water is never in sufficient quantity to pass its point of maximum density at the temperature of the receiver, and therefore to condense to the liquid state.

Commercial carbonate, $(\text{CO}_2)_2\text{OH}_2(\text{NH}_3)_3$, is most probably a third, and the only other single substance formed from the above mixture. The grounds for considering it to be a single substance are—(1) that it is formed so unfailingly and readily by the distillation of any of the true ammonium carbonates; (2) that it can be distilled, and its products again readily condensed to a substance of the same composition; (3) that its composition, when prepared under varying conditions, is closely in accordance with the calculated numbers; (4) that its composition is relatively a very simple one; (5) that ammonium carbamate combines apparently with acid potassium carbonate; and (6) that no other products can be prepared by distillation of uniform composition but this substance, the carbamate, and the acid carbonate, and be re-distilled and condensed into products of the same composition again.

The conditions which seem to be necessary to the formation of the commercial carbonate are—(1) the cooling of a mixture of two volumes of carbonic anhydride and three volumes of ammonia in presence of at least the calculated quantity of water; or (2) the cooling of a mixture of more than two volumes of carbonic anhydride to three of ammonia in presence of at least enough water, provided that some of this is in the liquid state; or (3) the cooling of a mixture of less than two volumes of carbonic anhydride to three volumes of ammonia in presence of enough water in the state of vapour at the temperature at which they combine.

ON SUPERSATURATED SOLUTIONS.*

THE following paper by Mr. Grenfell appeared in *Nature* for the 4th of August, 1870:—

The following experiments may be found interesting from their bearing on the latest theories advanced on the subjects on supersaturation and the so-called inactive state of bodies. Professor Tomlinson's theory is that a supersaturated solution adheres as a whole to a chemically clean surface, but that a differential adhesion takes place in presence of a chemically unclean surface, because the salt or gas adheres to such a surface while the liquid does not; the former is consequently liberated. The presence or absence of grease is then stated to constitute chemical uncleanness or cleanness. If a greasy surface can be rendered inactive, it is clear that both these propositions cannot be true; either grease is not of itself a cause of uncleanness, or unclean surfaces are not necessarily active ones. The following experiments prove that the fats may be rendered inactive by the same processes which are applied to rods of glass or metal.

1. A bit of composite candle was melted with a very little alcohol; a glass rod was dipped in, allowed to cool, passed through flame of a Bunsen's burner, and a drop of melted fat deposited on surface of supersaturated solution of zinc sulphate. The fat solidified without affecting the solution even on prolonged agitation. A crystal of the salt caused instant solidification.

2. Same solution boiled remained supersaturated for a fortnight with a crust of fat on the top.

3. Ordinary tallow treated as No. 1. Inactive in solution of sodic sulphate solution; touched with finger, crystallised at once.

4. Lard cleaned simply by melting on rod passed through

* Communicated by C. Tomlinson, F.R.S.

flame, allowed to cool, stirred in solution of sodic sulphate. Inactive. Other end of rod active at once.

5. Same solution boiled; cooled, stirred with rod, treated as the last, and left exposed to the air for 15 minutes. Did not crystallise. This experiment is interesting, as showing that greasy substances are not specially liable to be made active by exposure to ordinary air.

6. Some tallow was melted in a test-tube without precautions of any kind, and while melted was poured to the depth of half an inch on to solutions of ferrous, cupric, and sodic sulphates. In each case it was inactive. This is conclusive on the point in question.

Theoretical objections have been urged against the definition of chemical uncleanness, and I think this might now be surrendered.

Professor Tomlinson may very likely be right in looking to adhesion for an explanation of these phenomena; at all events, far greater probability seems to attach to this view than to that put forth by M. Gernez, adopted by Jamin, and even, I believe, favourably noticed by the Academy itself; which is that only a crystal of the same salt can induce crystallisation. This latter view is open to the theoretical objection that it necessitates our believing that all salts capable of supersaturation are everywhere and at all times present in the atmosphere. Mr. Tomlinson has shown experimentally that a crystal of the salt properly treated can be inactive in a solution of sodic sulphate.*

The following experiments show that an atmosphere presumably saturated with the salt may be inactive without any precautions whatever:—

7. Three solutions of sodic sulphate were prepared; a glass rod was dipped in melted tallow and left to cool for five minutes in a bottle of the salt, without touching the salt or the sides of the bottle. Then the three solutions were successively touched with the rod; inactive in all. Rod replaced in the bottle for ten more minutes; then all three again touched. The third crystallised after a minute or two. Rod replaced for fifteen minutes; active only in the second; replaced for fifteen minutes, active in the last. Thus this greasy rod was inactive in one of the solutions after an exposure of thirty minutes, and after being six times dipped in solutions of the salt.

8. An open test-tube, containing a strong solution of sodic sulphate, remained supersaturated for a week suspended in the same large bottle of the salt. The bottle was frequently moved without producing any effect. On removing the cork, the solution crystallised instantly.

On the whole I am afraid we must for the present fall back upon that refuge for the destitute, "Catalytic action."

J. G. GRENFELL.

Birmingham.

The following is Mr. Tomlinson's reply to the above:—

During the last two years, I have made a large number of experiments, in order to ascertain the function of oils and fatty bodies in determining the crystallisation of supersaturated saline solutions. The results of my inquiry are included in a paper which was read before the Royal Society on the evening of the 16th of June last; and I beg to refer to the abstract thereof in the *Proceedings*.

* It would seem from the experiments of Dr. L. C. de Coppet (which do not appear to be as well known as they deserve) that the treatment adopted by Mr. Tomlinson for rendering the sodic sulphate inactive really changes the salt. Dr. de Coppet finds that a supersaturated solution of sodic sulphate may be prepared by dissolving the anhydrous salt in cold water; and he writes—"I have arrived at the condensation of anhydrous sodic sulphate obtained by the efflorescence."

The ordinary salt with ten molecules of water, undergo a change of loses a proportion to temperatures superior to 33° or 34°; for the calculated from the efflorescence sulphate always causes the assumption that the salt solution of this salt, whereas anhydrous acid carbonate remains. *Id. Sc. Nat.*, x., p. 151. at 15°, so that it and therobable that the so-called supersaturated solubilities which seem anhydrous salt in a state of unstable disturbance to cause it to assimilate of acid carbonate they able compound.—*Ed. Nature.*]

I may, however, be permitted to make a few remarks arising out of Mr. Grenfell's paper.

According to my view, a *nucleus* is a body that has a stronger attraction for the gas, or the vapour, or the salt, of a supersaturated solution, than for the liquid that holds it in solution.

Nuclei, with certain limitations, cease to be such when made *chemically clean*.

A body is chemically clean the surface of which is entirely free from any substance foreign to its composition.

Thus, oils and fatty bodies are chemically clean if chemically pure and containing no substance mixed or dissolved that is foreign to their composition.

The limitations above referred to are two—(1) The oils, &c., when chemically clean, do not act as nuclei while in the mass, such as a lens or globule; but these oils, &c., whether clean or not, act powerfully as nuclei when in the form of thin films. (2) A liquid, at or near the boiling-point, is a supersaturated solution of its own vapour; and a *porous* body, such as charcoal, pumice, &c., whether clean or not, is a powerful nucleus in separating vapour.*

I have, on several occasions, taken the liberty of opposing M. Gernez's views, as to the action of nuclei. He supposes (1) that supersaturated gaseous solutions (soda-water, Seltzer, &c.) give off their gas to nuclei, by virtue of the air that these latter introduce into the solution; in other words, gas must escape into air, and the function of the nucleus is to carry down air; hence, rough bodies act better as nuclei than smooth ones. I have shown,† in a series of twelve experiments, that air is not a nucleus, and that rough bodies are inactive if *catharised* or made chemically clean. A rat's-tail file, for example, is a good nucleus, because it holds between its teeth that filmy kind of matter that is powerfully nuclear; and it is not easy to clean a body of this kind; but, when clean, it is quite inactive. So, a flint stone that has been exposed to the air, or handled, acts as a powerful nucleus; but, when broken, the newly-fractured surfaces are inactive, because chemically clean. And such surfaces are inactive because the gaseous solution adheres to them as a whole; whereas, if a clean body be handled, or exposed to the air, it becomes covered, more or less, with filmy matter, to which the gas adheres more strongly than the liquid, and hence there is a separation of gas.

There is, I think, abundant proof that air is not a nucleus; its function, if it have any, as regards the phenomena in question, being that of a carrier of nuclei. Proof, also, is wanting, I imagine, that, when a nucleus determines the crystallisation of a supersaturated saline solution, a salt of its own kind is present. When M. Gernez so laboriously prepared his nuclei, so as to free them from salt, he did not, perhaps, reflect that he was making them chemically clean. Of course, I fully admit that a salt of the same kind as the solution acts as a powerful nucleus; but, in order for it so to act, it must adhere more strongly to the saline than to the liquid portion of the solution. It may even happen that a crystal of the same kind, and of the fully hydrated salt, has no nuclear action, because it is in a perfectly catharised condition. And here I must refer to the objection raised by Dr. De Coppet, that, in one of my forms of showing the experiment, the hydrated crystals, say, of magnesian sulphate, being introduced into the neck of the flask while the solution was boiling, and so left in the covered flask while the solution cooled, such crystals became so changed by the heat as no longer to represent the normal salt; so that, when lowered into the solution, they formed a different salt, and, hence, were no test of the point in question, as to whether a salt of the same kind may be rendered inactive as a nucleus. I admit the criticism to be just, but, in my original account of the experiment,‡ I

* *Proc. Roy. Soc.*, No. 108, 1869.

† *Phil. Mag.*, Aug. and Sept., 1867. *CHEMICAL NEWS*, vol. xvi., pp. 54, 149.

‡ *Phil. Trans.*, 1868, p. 665. *CHEMICAL NEWS*, vol. xviii., p. 110.

did not rely upon one form. Highly-supersaturated solutions in clean tubes, plugged with cotton wool, were placed, when cold, over sulphuric acid, under the receiver of the air-pump, and left for some time *in vacuo*; when crystalline crusts of the normal salt formed on the surface, and these, by shaking, fell through the solutions without acting as nuclei; whereas, on removing the cotton wool in the presence of air, the solutions crystallised immediately into a solid mass. So, also, by keeping supersaturated solutions during some months, vapour of water escapes through the cotton wool, and a crystalline crust of the normal salt creeps up the air-filled portion of the tube; and this has no nuclear character, because the adhesion between it and the solution is perfect.

So necessary is the action of a nucleus in determining crystallisation in these solutions, that, if care be taken to exclude nuclei, highly-supersaturated saline solutions may, by reduction of temperature to 0°F ., or from that to -10°F ., be made solid; and, on placing the tubes in snow and water at 32° , the solids rapidly melt into clear bright solutions, without any separation of salt. These effects may be shown any number of times; but, whether the solution be solid or liquid, if the cotton wool be removed for a few seconds, crystallisation always sets in, in the case of the solid, during the melting; in that of the liquid, the effect is immediate.

With respect to the editorial note that the solutions of hydrated salts contain the anhydrous salt, I have shown, in my paper in the *Transactions*, and with still greater elaboration elsewhere*, that such is the case with respect to sodic sulphate. I insist on this point, as it is one of first-rate importance in considering the theory of supersaturated saline solutions. I endeavour to prove that it is the anhydrous salt in solution, by showing that, at various points of the scale, a sudden lowering of the temperature produces a shower of the well-known octahedral crystals of the anhydrous salt. I also explain, in my original memoir, that it is necessary for these crystals to be deposited before the modified seven-atom salt can be formed; and that, even when there is a copious deposit of this salt, the liquor above it is not, as Löwel supposed, the mother liquor of the seven-atom salt, but it is still a solution of the anhydrous salt. And, more than this, when the sudden change in the curve of solubility takes place at 33° or 34°C ., and there is, according to Gay Lussac's supposition, a change in molecular condition, it is still the anhydrous salt that is in solution.

CHARLES TOMLINSON.

Highgate, N., August 8th, 1870.

EXAMPLES FOR PRACTICE IN QUANTITATIVE CHEMICAL ANALYSIS.†

By FRANK H. STORER,

Professor in Massachusetts Institute of Technology.

SEVERAL teachers who have attended the free courses of instruction in General Chemistry and Qualitative Analysis established at the Institute of Technology, through the liberality of the trustee of the Lowell Institute, have expressed a desire to prosecute the study of Quantitative Analysis also,—at least, far enough to obtain a general idea of the methods actually employed in that branch of chemical art.

The object of the following communication is to show how readily this desire may be gratified, even without access to a well-appointed laboratory.

In most manuals of Quantitative Analysis, and in most of the laboratories established for teaching students who are to pursue chemistry as a profession, the subject is treated of in such manner that a costly balance seems to be absolutely essential for the conduct of accurate opera-

tions. The would-be amateur is usually disheartened at the first glance by this requirement, and led to regard the study as something not only occult in itself, but impracticable for him, because expensive.

It must be remembered, however, that, though now indispensable to the professed chemist, the delicate "chemical balance" is, comparatively speaking, a thing of yesterday. The science has actually been built up, for the most part, through the use of far rougher implements, such as may now be obtained almost anywhere for a few dollars. There is, in fact, no real difficulty in making thoroughly satisfactory analyses of a great variety of substances, by means of a cheap balance, if the operator will but work with tolerably large quantities of his materials.

The advantage in using a delicate balance consists chiefly in the time gained by operating upon small quantities. Other things being equal, a precipitate, which weighs only a few grains, may evidently be collected, filtered, and washed more readily than one weighing the same number of drachms.

The following analysis made under my direction, in the Institute's laboratory, by my assistant, Mr. A. H. Pearson, may serve as examples of what can readily be accomplished by a careful manipulator tolerably familiar with chemical principles. It may be remarked that several of these analyses are better than the average of analyses made with fine balances and small quantities.

The apparatus required for the following experiments consists of a couple of sheets of "Swedish," and five or six sheets of ordinary filter paper; two glass stirring rods; two glass funnels, each large enough to carry a six-inch filter; three or four glass beakers; a couple of glass flasks, one of them fitted with tubes as a wash-bottle; a crucible and an evaporating dish of Berlin porcelain; a Bunsen's gas-burner, or an alcohol lamp; and an iron ring stand, furnished with a rough sheet-iron saucer,—for use as a sand bath; a triangle of iron wire and a piece of wire-gauze four or five inches square. Instead of the ring stand, a tripod of stiff wire may be used. For experiment No. VI. a burette will be needed also.

The balance actually used in the experiments here recorded was an apothecary's "prescription scale," capable of carrying 60 grammes or more on each pan, and delicate enough to move distinctly with a weight of two milligrammes. It was made by Becker and Sons, of 18, Exchange Place, New York, and bought of their Boston agents, J. T. Brown and Co., corner of Washington and Bedford Streets, for 8.60 dollars in gold. The weights employed were a set of ordinary German gramme weights, worth five or six dollars.

With the exception of parts of Experiments VII. and VIII., all the operations described may be performed without trouble in any ordinary room. The evaporation of the acid liquor in Experiment VII. may be readily effected by placing the lamp, ring-stand, and evaporating dish in a not too tight wooden box out of doors.

EXPERIMENT I.—Determination of Iron by Precipitation as Sesquioxide.

Weigh out about 3 grammes of fine, tough iron-wire. Put the wire in a beaker of about a litre capacity, and pour upon it 30 or 40 c.c. of pure strong chlorhydric acid. Place the beaker on a sand-bath or piece of wire gauze above the lamp, cover it with a piece of window glass, and heat its contents gently, so that the iron may dissolve with tolerable rapidity, but without violent ebullition. When the iron has dissolved, add 10 or 12 c.c. of strong nitric acid to the solution and continue to heat the mixture. Through the oxidising power of nitric acid, the ferrous chloride will be changed to ferric chloride. Meanwhile, the liquid will become temporarily dark coloured by dissolving a quantity of the hyponitric acid, which results from the reduction of the nitric acid. But after a few moments the liquor becomes clear again, as the nitrous fumes escape, and then exhibits the characteristic

* CHEMICAL NEWS, vol. xx., p. 277.

† Communicated by the Author. From the *Massachusetts Teacher*.

reddish-brown colour of ferric chloride. As soon as the temporary dark colour has disappeared from the solution, lift the cover of the beaker, and by means of a wash-bottle rinse back into the iron solution any particles of liquid which may have been thrown up during the action of the acid and left adhering to the plate. Dilute the iron solution with pure water enough to nearly fill the beaker, stir the mixture with a glass rod, and transfer half of it to another beaker of the same size as the first. Heat the contents of each beaker almost to boiling, stir the liquor, and add to it, little by little, ammonia water, until the odour of the ammonia persists. A couple of filters of "Swedish paper," each of six inches diameter, will be sufficient to collect the whole of the hydrated sesquioxide of iron thus thrown down. To facilitate the process of filtering and washing, proceed as follows:—Let the contents of each beaker stand at rest for a few moments in order that the hydrate of iron may settle; then pour into the filter the tolerably clear liquid which floats above the precipitate, and pour a quantity of boiling water upon the precipitate in the beaker. As soon as the mixture of precipitate and water has settled again somewhat, pour the tolerably clear supernatant water into the filter and again pour hot water upon the precipitate in the beaker. Repeat this process of washing by decantation, some eight or ten times; then wash out the whole of the precipitate from the beaker into the filter, by means of a wash-bottle, and continue to pour hot water upon the contents of the filter, until the last traces of chloride of ammonium have been removed. When the last drops of wash-water have drained away, cover the funnels with paper to protect the precipitates from dust, and set them aside in a moderately warm place.

Transfer the dried precipitate from the filters to a porcelain crucible of known weight, burn the filters upon the cover of the crucible until the last portions of carbon are destroyed, add the ashes to the precipitate in the crucible, cover the latter, and heat it strongly for eight or ten minutes over a Bunsen lamp. In burning the filters, it is well, towards the close, to press down the unburned carbon against the hot porcelain by means of a stiff wire.

After the crucible has been allowed to become cold, weigh it with its contents. This weight, minus the original weight of the crucible and that of the filter ash (for which an allowance of 0.3 per cent of the weight of the paper may be made), will give the weight of the sesquioxide of iron, whence the weight of iron may be calculated by the following proportion:—

Wt. of a molecule of Fe_2O_3	Wt. of the : 2 atoms of Fe therein contained	Wt. of : : Fe_2O_3 : X. found.
---	---	--

Starting with 3 grammes of metallic iron, Mr. Pearson obtained 4.282 grms. of Fe_2O_3 (= 2.9974 grms. Fe), or in terms of per cents, 3 : 2.9974 = 100 : 99.91 per cent.

(To be continued).

ON GLAUKOPYRITE, A NEW MINERAL.

THE following abstract of a publication by F. Sandberger is taken from *Verhandlungen der K. K. Geologischen Reichsanstalt*:—

In pieces of coarsely-lamellar calc-spar, brought by Dr. Schiöberg from the mines of Guadalcanal, Andalusia, different ores were observed, the examination of which was undertaken by Professor Sandberger. This resulted in the proof of the existence of a new mineral, which occurred, together with solid, crystallised fahlore, proustite, and scattered bunches of lamesonite, the new mineral greatly predominating in quantity. It appears in kidney-shaped aggregations, composed of extremely thin shells of finely-granular structure, which repeatedly alternate with thin

layers of calc-spar, and rarely with those of proustite. The kidney-shaped masses are entirely surrounded with lamellar calc-spar; and, if this is removed with acetic or dilute muriatic acid, the surface appears to be formed by numerous, mostly very small, crystals, in comb-like aggregations. On the layer of these crystals, Sandberger could discern, with a magnifying glass, as a fundamental type, twins of two flat rhombic tables, lying crosswise to each other, and presenting the habitus of cerussite—twins of similar combination; besides these, triplets can be distinctly recognised. The streak of the fine granular masses is shining, but the lustre of the crystal faces is feeble, except certain faces, supposed to be normal prismatic and brachy diagonal prismatic, which have a strong metallic lustre. The colour of the mineral is light lead-grey to tin-white, the streak greyish black; hardness, 4.5; sp. gr., 7.181. In contact with the air, the mineral tarnishes slowly, first assuming a blackish, afterwards a yellowish brown, and finally a blue colour. An analysis made by R. Senfter, in the laboratory of Dr. Petersen, gave the following result:—

Sulphur ..	2.36
Arsenic ..	66.90
Antimony ..	3.59
Iron ..	21.38
Cobalt ..	4.67
Copper ..	1.14

100.04

The new ore belongs, consequently, to the group of arsenical pyrites, and comes nearest to the mineral from Wolfach, which Sandberger identified with Briehaupt's geyerite.

But, as neither form nor hardness, nor specific gravity and colour, are the same in both, and as, moreover, the copper observed in the new mineral is wanting in geyerite, Sandberger proposes, for this new ore from Guadalcanal, the name *glaukopyrite*, and gives for its composition the formula—

NUCLEI AND SUPERSATURATED SALINE SOLUTIONS.

By ARCHIBALD LIVERSIDGE,
Associate of the Royal School of Mines.

I FORWARD the following account of some experiments made upon supersaturated solutions of sodic sulphate, (and attempted explanations of the action of nuclei upon the same, which have presented themselves to my mind from time to time), in the hope that they may not be entirely devoid of interest to some of your readers.

I may state in the outset, that the experiments were carried out in April, May, and June, 1869, since which date I have repeated and confirmed them all, in some cases, perhaps, a score or more times.

Mr. Tomlinson has already shown that air itself is not a nucleus, nor is a clean crystal of sodic sulphate; he has also shown that a "chemically unclean" rod, or other solid body, may be rendered clean by heating it in the flame of a spirit lamp, or by boiling it in the solution itself. He has also given us a definition of a nucleus:—"A nucleus is a body that has a stronger adhesion for the salt than for the water which holds the salt in solution, a state of things brought about by the absence of chemical purity" (see *CHEMICAL NEWS*, vol. xviii., p. 3); and in vol. xiv., p. 128, he says "this action of solid bodies is due to the greasy film which, after exposure to the air, they are sure to acquire."

My own views regarding the action of nuclei were just the reverse of that given in the above definition. I imagined that the nucleus was a body which had a greater attraction for the water of the solution than for the salt in solution, and I see no reason why this should not be so.

In order to prove, if possible, the correctness of this speculation regarding the nature of nuclei, the following experiments with various dehydrating substances were made:—

Expt. 1.—Placed some calcic chloride in a thin glass bulb, fused the chloride within the bulb, then sealed up the tail, and cleaned the exterior of the bulb by holding it by a pair of forceps in a spirit lamp flame; then dropped it into a flask containing the supersaturated solution. No effect was produced, thus showing that no nuclei were carried in by it; the bulb was then broken by means of a clean glass rod. The solution now had free access to the calcic chloride, but no effect was produced, the solution still remaining liquid.

Expt. 2.—Quick-lime was heated to redness in a bulb, and the experiment conducted as last. No effect.

Expt. 3.—Crystals of chromic acid were likewise tried. No effect.

Expt. 4.—Phosphoric anhydride was also employed, but still without determining the crystallisation of the salt.

cork bearing the bulb of alcohol, or acid substituted for it; now, by loosening the glass rod stopper, the liquid under trial was run in. In the case of sulphuric acid, the smaller the drop the better, so as not to raise the temperature of the salt solution. But, as was anticipated from the previous results with calcic chloride, &c., no effect was produced.

These experiments seem to prove that nuclei do not act by *chemically* abstracting a portion of the water.

Throughout, in each and every case where the substance under experiment did not act, the solution was proved to be in good condition, by dropping into it a dirty crystal or rod.

It next occurred to me, that perhaps the substances under trial acted as nuclei in virtue of their power of abstracting water *mechanically*, absorbing the water within their pores, and rejecting the salt.

At first, this conclusion seemed to be borne out by experiment; for, on dropping into a supersaturated solution pieces of cork, paper, wood, charcoal, cotton, silk, wool, sponge, bone-earth (fragment of a cupel), burnt clay, sulphur, &c., crystallisation was immediately set up.

And I found that if I previously soaked them in water for a few minutes, no matter how dirty and greasy they might be, they now no longer behaved as nuclei; and, to render them as dirty as possible, I rubbed them over with

Expt. 5.—The apparatus as sketched (Fig. 1) was then set up.

While the solution was still hot, air was drawn through the apparatus for some little time, so as to effect the removal of nuclei from the apparatus itself. On the solution becoming cold, air was again caused to pass through, to ascertain the efficiency of the cotton wool and sulphuric acid tubes as filters; they answered perfectly, for no nuclei gained access to the solution. Now the phosphorus was ignited, and a gentle current of air drawn through, carrying with it the phosphoric anhydride thus formed; but, as in the case of the experiments with bulbs, the anhydride had no effect upon the solution. On removing the filter of cotton wool, and again exhausting (as was to be expected), solidification immediately took place.

Several trials were then made with absolute alcohol and concentrated sulphuric acid; the contrivance sketched in Fig. 2 was used (this kind of bulb is largely used at the Royal College of Chemistry for a carbonic anhydride estimation apparatus).

It consists of a bulb tube, *a*, having a knot tied at the end, *b*; this, in conjunction with a stopper, made of a piece of india-rubber tubing and glass rod, enables you to completely control the delivery of the fluid.

The solution was allowed to cool in the flask closed by a plug of cotton wool; this plug was then removed, and the

grease, then rolled them on the dusty carpet; in fact, made them as filthy as possible, but still, on saturating them with water (which was used cold, and very dirty), they were rendered inactive as nuclei.

When, instead of moistening them, I placed them in the spirit-lamp flame and scorched them, their power of setting up crystallisation was also effectually destroyed.

Again, it was found that portions of wood, cork, charcoal, sulphur, &c., taken from the interior of a mass, were perfectly inactive, thus showing that the property was not inherent in the bodies themselves.

When it is found that, by simply placing a greasy rod, pellet of wood, &c., into water for a short time, they are rendered inactive, we cannot attribute their activity, before moistening, solely to the repellent action of the film of grease, for they are just as greasy, after this treatment with water, as before; if it were due to the grease, then their behaviour, before and after immersion, would be the same.

In order to ascertain what effect grease had upon a supersaturated solution the following experiments were made:—

Expt.—A glass rod was first cleaned in the spirit lamp, and then dipped into a bottle of hair-oil, and thence transferred to the flask. No effect; inactive.

Expt.—Wax was melted on a rod.* No effect; the flame cleaning both the rod and the wax.

* Since writing the above, a letter from Mr. J. G. Grenfell has appeared in *Nature* for August 4, 1870, upon the same subject.—A. L.

Expt.—Wax, taken from the middle of a lump. No effect; inactive.

Expt.—Dirty wax, which previously behaved as a nucleus, after standing in water for some time was thus rendered inactive.

An active rod is not rendered inactive by soaking in methylated spirit, hair-oil, nor benzol, although themselves inactive. But sulphuric acid, hydrochloric acid, solution of ammonia, and aqueous solutions of various salts, do render such a rod inactive. The sulphuric acid may act by destroying the nuclei, while the others may furnish water to them, and so prevent them from acquiring it at the expense of the solution.

All that grease seems to do is simply to facilitate the collection of nuclei; a spot of grease on cloth is always shown up by its acquiring a different colour, due to the adhesion of dust.

From the foregoing, it appears that the substances upon which I have experimented do not themselves behave as nuclei (although other bodies, yet to be tried, must), but that, by exposure to the air, and contact with dusty objects, this property of determining the crystallisation of solutions is imparted to them.

It is highly probable that nuclei may be found to consist of minute organisms and germs floating about in the air, the activity of which is destroyed by heat and by moisture.

I have only been able to make two experiments with microscopic organisms, and they, of extremely little value.

Expt.—Dry lycopodium spores; these behaved as nuclei, or contained something else which did.

Expt.—Wet lycopodium; inactive.

Expt.—Water, containing infusoria, such as *Amæba*, *Vorticella*, *Paramæcia*, &c.; inactive.

I may, perhaps, repeat, without attaching too great a value to the results furnished by the above experiments—(1) That it is not impossible that nuclei consist of microscopic organisms, which act by abstracting water, the action being set up at a point from which it is propagated throughout the mass; (2) that they are rendered inactive by heat, because it entirely destroys them; (3) that their action is arrested by previous saturation in water, because they then can no longer abstract water from a saline solution.

Shortly, I hope to have the results of some further experiments.

London, July 12th, 1870.

ON THE ANILINE OR COAL-TAR COLOURS.*

By W. H. PERKIN, F.R.S.

(Continued from p. 82).

BEFORE making any further remarks upon the coal-tar colours, I wish to draw your attention to some of their applications to the arts.

I have told you that most of the coal-tar colours contain carbon, hydrogen, and nitrogen, and that they are generally organic bases. They differ essentially from most of the vegetable colouring matters, which contain, with but few exceptions, only carbon, hydrogen, and oxygen, and are weak acids. You will thus understand that many difficulties had to be encountered in their application for dyeing and printing, because they would not combine with the ordinary mordants used for the colouring matters of woods, as alumina and oxide of tin. These observations refer to the dyeing and printing of vegetable fibres, and not to silk or wool, as these materials absorb the coal-tar colours without the intervention of a mordant.

In silk dyeing, the principal difficulty experienced in applying the coal-tar colours was owing to their great

affinity for the fibre, thus preventing the dyer from obtaining an even colour, especially when dyeing light shades.

After a time, however, it was found that this obstacle could be overcome by dyeing the silk in a weak soap lather, to which the colour had been added. This not only caused the dyeing to proceed with less rapidity, but also kept the face of the silk in good condition. Silk dyed by this process is left soft, but may afterwards be rendered hard or "scoop" by rinsing in a bath of slightly acidulated water.

This process was first used for dyeing silk with the mauve or aniline purple. It has, however, been since found suitable for nearly all the aniline colours, as magenta, Hofmann, and Britannia violets, &c. For dyeing silk with coal-tar colours of an acid nature, such as picric acid, dinitronaphthol, &c., the silk is simply worked in a cold aqueous solution of the colouring matter, sometimes slightly acidulated, as when using the sulphoacids of aniline blue or soluble blue. The process of printing silk with aniline colours is comparatively simple. An aqueous or alcoholic solution of the colouring matter is thickened with gum senegal, printed on with blocks, and, when dry, exposed to the action of steam for about half an hour. The gum is then washed off, and the goods finished.

In my last lecture I referred to the formation of two colourless products from magenta, the one called leucaniline, and the other hydrocyanrosaniline.

Some few years since, it was found that if silk dyed with magenta has the reagents necessary for the formation of these colourless products printed upon it, what is called a discharge style can be produced. One of the substances used for effecting this change is powdered zinc mixed with gum. This process also applies to all the coloured derivatives of magenta, and yields better results than can be obtained by printing on the colouring matter and leaving the white parts, because the colours are always clearer when dyed than when printed. But this is not all. When printing two colours on silk, say a pattern with a green ground and purple spots, two blocks have to be used, the one for the ground and the other for the spots; and, when removing the first block, the silk often moves slightly; therefore when the spots are put in by the second block, they do not exactly register, and thus an imperfect result is obtained. This difficulty, however, can be avoided by taking silk dyed with any of the derivatives of magenta, and printing it with the discharge previously mixed with the colour it is desired to introduce, of course employing a colouring matter which is not affected by the discharge, as aniline purple, aniline pink, &c. This discharge style has only been employed for silk at present.

We will now turn our attention to the methods of dyeing wool. These methods, as a rule, are very simple, the wool being merely worked in a hot aqueous solution of the desired colouring matter, no mordant being required. Acids are generally found to be injurious, a neutral bath being preferred, and the operation finished by bringing the temperature nearly up to that of boiling water.

With the blue known as Nicholson's blue, the process of dyeing is different to that just given, and consists of two distinct operations, the wool being first worked in an alkaline solution of the colour, which gives it a kind of grey or slate shade, and then in an acid bath, which develops the colour.

The printing of wool is similar to that of silk, the colouring matter being simply thickened with gum, printed on the goods, steamed, and then washed.

The dyeing of cotton with aniline purple at first presented many difficulties. This colouring matter was found to be capable of producing a very beautiful colour without a mordant, and it was proposed to employ it in this manner, but the colour thus obtained would not bear washing, being nearly all removed with hot water and soap. Mordants, such as alum, were then experimented with, but these gave no results. After some time Mr. R. Pullar and myself found a method of applying this colouring

* The Cantor lectures, delivered before the Society of Arts.

matter to cotton, which is based upon the insolubility of the compounds it forms with tannin. In using this process the cotton is first soaked in a decoction of sumac or some other tannin agent, then in a solution of stannate of soda, and, lastly, in water, slightly acidulated with sulphuric acid. The cotton thus prepared contains an insoluble compound of tin and tannin, and which possesses a great affinity for aniline purple. The stannate of soda may be replaced by alum, or a solution of tin salt. This method of preparing cotton has been found suitable for nearly all the aniline colours discovered since the mauve, and is now almost universally employed in Great Britain for cotton dyeing. Other processes have been proposed for cotton dyeing, but are not so generally employed as the one just described.

We now pass on to the application of coal-tar colours to the art of calico printing. The mauve, when first introduced, was applied to printing in a very simple manner; the colouring matter was merely mixed with gum and albumen, printed on the goods and steamed; by this process the albumen became insoluble, and fixed the colour. Caseine and gluten were sometimes used as substitutes for albumen. Being dissatisfied with this mechanical mode of applying aniline purple, in conjunction with Mr. Grey, I made a number of experiments with a view of obtaining some more chemical method of fixing this colouring matter, and at last succeeded. The process proposed consisted in printing the pattern with a salt of lead, then converting this into the oxide or a basic salt, by passing the goods through an alkaline solution. Thus prepared, they were worked in a boiling solution of aniline purple in soap. In this way a very pure colour was obtained on the mordanted parts, the soap keeping the whites pure. This process, however, was of very limited application, as it could only be applied for single-colour patterns. After this, several processes were patented for the use of tannin for fixing the mauve; these were based upon the method of dyeing cotton previously mentioned, and some very fast results were obtained, but as these methods are now out of use, I will not describe them further.

The process now nearly universally employed in the north was discovered by M. Alexander Schultz and myself; it consists in printing the colouring matter with a mordant composed of a solution of arsenite of alumina in acetate of alumina. On steaming the cloth printed with this mixture for about half-an-hour, the colour is firmly fixed in the fibre. After steaming, the goods are generally soaped, and then finished. One of the great advantages of this process is that it can be worked in patterns with a great variety of colours, and is also suitable to nearly all the aniline colours, as well as the mauve, yielding shades of great brilliancy.

During the last few years, much attention has been given to the application of aniline black to calico printing. This substance is not prepared in the separate condition, but formed on the fabric; it is produced by printing a mixture of a salt of aniline, chlorate of potassium, and sulphide of copper, thickened with starch, upon the goods, and in this manner a dull grey impression is obtained; but, after three or four days ageing, this changes to a dark olive, and is then rendered perfectly black by passing the goods through a dilute solution of carbonate of soda. This colour is very fast, but is inclined to acquire a slightly green shade by long exposure to the air. Unfortunately, it cannot be printed on with other colours, because, when steamed, the cotton is destroyed by the acid character of the mixture employed for its formation. It can, however, be printed on at the same time as madder mordants, and these can be afterwards dyed with a lead mordant, so that when passed through bichromate of potassium, a pattern with black and yellow or orange can be obtained.

The aniline colours have produced quite a revolution in the arts of dyeing and printing, and have made these processes far simpler than they were, and there is such a

variety of shades of colour now sent into the market, that the dyer or printer has little else to consider than the intensity of the colour required; and, in fact, if a dyer has a large order to execute of a particular shade of colour not in the market, he will not trouble about matching it himself, but sends to the colour manufacturer to supply him with a product capable of yielding the required shade.

Besides dyeing and calico-printing, several other branches have benefited by the coal-tar colours, such as the arts of lithography, type-printing, paper-staining, and colouring, &c. Before they could, however, be used for these various purposes, it was necessary that they should be made into lakes or pigments, by union with alumina or other suitable base; but, as most of the aniline colours are of a basic nature, it was found impossible to combine them directly with a metallic oxide like alumina; advantage was, therefore, taken of their affinity for starch granules, and some very brilliant products were obtained by dyeing powdered starch with the cold aqueous solution of these colouring matters. These starch powders, however, are wanting in covering power or body, so that other processes had to be sought for, and now these lakes are made upon an alumina base, by the intervention of tannin or benzoic acid.

Many attempts have been made to prepare a pigment from rosolic acid or aurine, and this, to some extent, has been accomplished by precipitating a solution of the colouring matter with alumina; by this process, a bright orange-scarlet coloured product can be obtained; it is, however, only suitable for paper-staining. I have, therefore, lately been further experimenting in this direction, and have succeeded in forming a very brilliant scarlet pigment, which can be used for printing inks and a variety of other purposes.

Upon the table there are some specimens of magenta, Britannia violet, aniline blue, green and orange lakes, and also some very beautiful and intense-coloured preparations of coal-tar colours, now generally called carmines. These lakes, when ground with printers' varnish, produce printing inks of very great brilliancy, and are extensively used for this purpose; and Mr. Hanhart, whose name is so intimately connected with the art of lithography, has most kindly furnished me with the various illustrations of the application of these products to lithographic printing for this lecture.

These lakes, in a wet condition, are being largely used for paper-staining, and also for paper-colouring, as well as for a variety of other less important purposes.

The peculiar bronze surface produced by evaporating a solution of an aniline colour, has been taken advantage of by the manufacturer; and all the bronze bonnets, hats, flowers, and feathers, so much worn in the autumn of last year, derived their lustre from aniline colours. When first employed for this purpose, no fixing agent was used with them; and, as they are mostly soluble in water, a shower of rain was often found to cause beautiful purple drops to fall from these bronzed bonnets and hats, and produce a kind of mottled pattern upon the white collars, and sometimes even upon the face of the wearer.

Aniline colours are used for writing inks, colouring soap, &c.; but, as these applications are only of small importance, in a commercial point of view, I will not spend time in speaking about them.

(To be continued.)

MISCELLANEOUS.

London Institution.—On the 10th inst., Dr. J. P. Gassiot, F.R.S., one of the Vice-Presidents of this Institution, distributed the prizes awarded, and certificates granted, to students who passed the examinations in Physics, Chemistry, and Botany, based upon the courses of Educational Lectures delivered, during the past session, by Professors Guthrie, Bloxam, and Bentley. First-class

prizes were obtained by Edmund Strode, A. J. Richardson, and Emma Ball; second-class prizes by T. Lyon, Esther Greatbatch, Annie Piper, Isidore Harris, E. M. Hutton, A. J. Wallis, and Ellen Benham. Dr. Gassiot stated that Professor Odling had consented to open the coming session with a course of Educational Lectures, "On Chemical Action," and that after Christmas Professor Huxley would deliver a course, "On the First Principles of Biology."

Utilising a Burning Coal-Mine.—In the environs of Dudley there was formerly a coal-mine on fire. The snow melted in the gardens as soon as it touched the ground. The gardeners gathered three crops a year; even tropical plants were cultivated; and, as in the Isle of Calypso, an eternal spring prevailed. In another Staffordshire colliery, the firing of which dates many years back, and which is called by the inhabitants "Burning Hill," it was noticed, as at Dudley, that the snow melted on reaching the ground, and that the grass in the meadows was always green. The people of the country conceived the idea of establishing a school of horticulture on the spot. They imported colonial plants at a heavy expense, and cultivated them in this kind of open-air conservatory. One fine day the fire went out, the soil gradually resumed its usual temperature, the tropical plants died, and the school of horticulture was under the necessity of transferring their gardens elsewhere.—*Underground Life.*

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, August 8th 1870.

This number, an unusually small one, contains the following original papers relating to physico-chemical and collateral sciences:—

Relation existing between the Specific Heats and the Coefficients of Expansion of any Substance.—M. Phillips.—An algebraico-physical paper.

Decimal Division of the Quadrant.—A. D'Abbadie.—Abstracts of two letters on this subject from MM. Radau and Airy.

Estimation of the Rapport of the Two Specific Heats of Gases.—MM. Jamin and Richard.

Reply to the Papers Published by H. Sainte-Claire Deville on the 18th of July last.—M. J. Jamin.—Algebraico-physical papers.

New Experiments on the Armatures and the Fixed Plate of Holtz's Electrical Machine.—M. Laborde.—The author describes some of the experiments made by him with a Helmholtz machine, made by converting an ordinary electrical machine.

Lithological Map of the Mouth of the Seine.—M. Delesse.—This map represents the geological formations met with at the mouth of the river above named, and along a portion of the coast. It appears that the same geological formations which are predominant in the parts of France bordering on the sea, in the vicinity of the mouth of the Seine, extend to a great distance under the sea.

Researches on the Toxicological Effects of the M'Boundou, or Icaja, a Poison in Use at Gabon.—MM. Rabuteau and Peyre.—It appears that, at Gabon, a French settlement on the west coast of Africa, there is in use a vegetable poison, locally known as *m'boundou*, or *icaja*. That substance is the root of a plant which is not further specified. The authors have been experimenting with this substance, which, even in very dilute decoctions, is very bitter, and appears to contain one or more alkaloids, since the aqueous decoction is largely precipitated by iodide of potassium, and also by phospho-molybdic acid. The poisonous effects of this substance bear some similarity to the effects of brucia, but the authors state that, under certain conditions, this poison does not hurt men. Some of the lower animals are readily killed by it; a dose of 3 milligrams of the alcoholic extract, placed under the skin of a frog, kills it; and rabbits and dogs are killed by doses of from 15 to 25 centigrams of the same extract introduced into the stomach.

The larger portion of the time this meeting lasted has been devoted to discussion on the *Phylloxera vastatrix*, and the best means of getting rid of them from the vineyards. The President announced that the next meeting would take place on Tuesday, the 16th, instead of on Monday, the 15th of August, in consequence of the last-named day being a high festival day. The election of a new corresponding member for the Natural History Section is postponed for three months.

Revue Hebdomadaire de Chimie, July 14, 1870.

Delaurier's Galvanic Element with only One Liquid.—The description, elucidated by a cut, of a galvanic cell composed of zinc and carbon placed in a fluid made up of 40 parts of water, 4½ parts of bichromate of potassa, 9 parts of concentrated sulphuric acid, 4 parts of sulphate of soda, and 4 parts of the double sulphate of potassa and iron. This element produces a very regular current. The zinc need not be amalgamated, and no gas is evolved.

Galvanometer with Vertical Needle.—M. Bourbouze.—The author's description of this instrument is illustrated by woodcuts. The chief aim of this contrivance is to render slight deviations of the needle visible to a large number of students at a time.

July 21, 1870.

Estimation of Nitrates in Potable Waters.—M. Scheurer-Kestner.—The author has tested a method for this purpose, originally devised by Dr. Goppelsroeder, and executed in the following manner:—To 50 c.c. of the water to be tested for nitrates are added 100 c.c. of concentrated and pure (free from nitrous compounds) sulphuric acid; to this mixture, which becomes very hot, a weak solution of indigo is added from a burette. The fluid becomes yellow, and, at the end of the operation, green-coloured. The author of this paper does not state the means of titrating the indigo solution, so as to render its use a suitable means of quantitative estimation; but he simply states that, after proceeding with the experiment as just mentioned, another experiment is made, wherein, instead of the addition of sulphuric acid to the water, there is added to it the quantity of c.c. of indigo solution first found necessary to produce a reaction.

Description of an Apparatus for the Continuous Preparation of Carbonic Acid, and of Lime, by One Operation.—A. Perret.—This paper, accompanied by woodcuts, describes, at length, a contrivance especially suited for beet-root sugar works, to decompose, by the joint agency of red-heat and steam, limestones in such a manner as to make the escaping carbonic acid gas available for use in the beet-root sugar manufacture.

Les Mondes, July 21, 1870.

Higher Public Instruction in France.—From a circular addressed to the recteurs by the Minister of Public Instruction, it appears that the French Government intends to lay out a large sum of money for improving, repairing, and completing the buildings (inclusive of laboratories, botanical gardens, &c.), museums, and scientific collections, libraries included, and for the expenses of heating and lighting rooms, halls, and other places adapted to the use of the various divisions of the Université de France, and the colleges and schools connected therewith.

Utilisation of Vine-Leaves and Cuttings of Young Vine-Twigs.—J. Guyot.—It appears that the materials alluded to are now partly given to the cattle in fresh state, and are partly salted for winter forage. Since France possesses 2,500,000 hectares of vintage-ground, the green materials mentioned will yield, according to the author, a sufficient quantity of food for cattle, at the rate of 20 kilos. per head for at least 100 days.

Geological Alpine Congress.—A number of scientific men, inhabitants of the Helvetic Republic, intend to hold, on August 31st and two following days, at Geneva, a meeting, chiefly with the view of starting a well-planned geological study of the larger chain of the Alps by Swiss, French, and Italian geologists. The well-known M. F. J. Pictet is one of the promoters of this meeting.

July 28, 1870.

Crystallisation of Iron and Steel.—Dr. Schott.—The author has examined a large number of samples of iron and steel, microscopically, and states that his observations lead him to consider that, the more regular and small the crystals are of which iron and steel are always composed, the better the metal. Moreover, in the good qualities of these substances the crystals are placed very regularly near each other.

Uniformity of Time for Military Camps.—Rev. F. Moigno.—The author discusses, but does not exactly describe, an instrument which appears to be of great utility for regulating and adjusting clocks and watches, and which is so portable and readily put together that any soldier may be left in charge of it. The price of this piece of mechanism is only 22 francs annually.

August 4, 1870.

Hygienic Vinegars.—A. Servel.—The author purifies wine vinegars, by a series of operations, not specified, so as to render them highly pleasant, strong, agreeably acid liquids, especially adaptable to being mixed with water, and thus rendering it (even when otherwise rather unpleasant) a refreshing, wholesome, and thirst-quenching fluid, highly recommended above the use of spirits in armies and navies,

also on account of the tonic properties the vinegars alluded to appear to possess.

Economical Candles.—M. Sokolnicki.—A paper, illustrated by several woodcuts, on the best plan for the manufacture of candles so as to make them give the most and best light and provide for complete combustion of the materials they are made of, with the least possible expenditure at the same time.

New Electric Battery Invented by M. Chutaux.—(Reported on by R. Francisque-Michel.)—A lengthy report, illustrated by a series of woodcuts. It appears that the results obtained are—

	Electromotive force.	Internal resistance.
Chutaux battery	11'400	6'00
Marié-Davy battery	8'192	5'50
Daniell battery	5'973	9'31
Peroxide of manganese battery	7'549	4'00

Cosmos, July 30, 1870.

Historical Facts about Potatoes.—Marshal Vaillant.—This well-known vegetable, first imported into Europe from Peru by Francis Drake, remained a very long time almost unknown; it was not cultivated in Germany until after 1710, and then only in gardens. Its introduction into France, from Germany, dates about 1749, and it never was generally introduced in the last-named country until about 1820. In the south of France, potatoes are comparatively rare, and rather an expensive vegetable, as compared with lentils, beans, &c.

Purification of Dirty Water.—S. Meunier.—Since, in dry seasons, any water may be of high value, at least for cattle-drinking, the author advises to place, in a large-sized cask, a false bottom perforated with some holes; and to put on that bottom, first, clean pebbles, next, well-washed sand, then a layer of coarsely-granulated charcoal, and over all this a piece of canvass. The water, even that accidentally standing in shallow ditches after a shower of rain, may be poured into this filter, and thus become available for cattle-drinking, though it may not be quite clear.

August 6, 1870.

Cause of the Fatigue to the Eyes caused by Artificial Light.—V. Meunier.—The author states that the great difference between sun and artificial light is due to the fact that, of the light emitted from the former, about half the quantity of rays are luminous and calorific at the same time; but, as regards our artificial light, for ordinary oil (colza oil), the amount of non-luminous, yet calorific, rays is 90 per cent; for white-hot platinum, 98 per cent; alcohol flame, 99 per cent; electric light, 80, and gas-light, 90 per cent; while for petroleum and paraffin oils, the amount is 94 per cent. It is this large quantity of calorific rays in artificial light which causes the fatigue to the eyes; but this inconvenience may, according to the author, be almost entirely obviated by intercepting the thermic rays by glass, or, better yet, mica plates. The use of these renders the light soft and agreeable to the eyes.

Possibility of Obtaining Luminous Signals Visible at Great Distances.—Dr. Delaurier.—The author proposes the use of galvanic electricity, so applied as to have the effect of producing what, in light-house terminology, is known as "flashing light." The idea of the author is to bring this into practice by means of a peculiar induction apparatus, so contrived as to cause the least possible expenditure of electricity, and to interrupt the current, so that only by the passage of a spark between the carbon-points at intervals of from two to five seconds of time, a luminous flash be produced, visible, even in foggy weather, at a great distance.

New Use for Hyposulphite of Soda.—S. Meunier.—The author states that experiments made with this salt have proved it to be very superior for use for washing linen to the carbonate of soda now in use; it has no corrosive action, and does not cause a yellow colouring of the fabrics after some time. Borax, largely used in the Netherlands and Belgium, is a better substitute still, and, by its use, white fabrics assume an agreeable bluish hue, which, in many instances, renders the subsequent use of washing-blue unnecessary.

A New and Highly-Recommended Book.—At one of the late meetings of the French Academy, M. Dumas spoke in highly-eulogising and, to the author, complimentary terms, on the work just published by M. Louis Figueur, which bears title, "Armes de Guerre et Bâtiment Cuirassés." In this work, illustrated by 237 engravings, the author gives an accurate description of all the contemporaneous arms of war—various kinds of guns, pistols, &c., mitrailleuses inclusive, and of iron-clad ships, as in use by different nations. The price of this book is 3 francs 50 centimes.

Monatsberichte der Königlich Preussischen Akademie der Wissenschaften zu Berlin, May, 1870.

This number contains the following original papers relating to chemico-physical and collateral sciences:—

Some New and Remarkable Properties of the Diametral Conductors of the Electro Machine, and Description of a New Kind of Double Machine the Construction of which is Based upon a New Principle.—Dr. J. C. Poggendorff.—A lengthy memoir, accompanied by engravings.

Composition of the Meteorites of Shalka and Hainholz.—Dr. Rammelsberg.—This paper is chiefly written with the view of proving that the assumed existence of a peculiar mineral, which was named shalkite, and obtained from the meteorite of Shalka (Bengal,

where the stone fell on the 30th of November, 1850), is erroneous, inasmuch as the author's analysis of this meteorite proves it to be, mineralogically, a mixture of broncite, olivine, and chrome-iron ore; while the Hainholz meteorite (the time when this mass fell is uncertain; the stone was found in 1856, near Paderborn, Prussia, by Dr. Mühlendorff) also consists of olivine and broncite, in addition to meteoric iron. The lengthy memoir contains the results of a series of analyses of the meteorites alluded to, but space forbids us to enter into more details here.

Journal de Pharmacie et de Chimie, July, 1870.

This number contains the following original papers and memoirs:—

Method for Readily Testing the Fatty Oils.—Dr. Massie.—In order to test the purity of the oils, the author employs nitric acid (sp. gr. of from 1'38 to 1'41) and metallic mercury. Five grms. of this acid, and 10 grms. of the oil to be tested, are mixed together in a test-glass of 100 c.c. capacity, and the mixture stirred for a couple of minutes. The liquid is then left standing; and, when the fluid has separated into two layers, the colour of these layers is noted. This colouration may be from greenish white to deep brown for the superior, or lighter layer; while the colouration of the acid, always less intense, will vary from light yellow to deep yellow, or even rose-red. After a while, 1 grm. of metallic mercury is added, the final result of which addition will be the solidification of the bulk of the oil in most cases. There is added to this paper a lengthy series of description of the phenomena observed when various oils, and mixtures of different oils, are treated by the reagents alluded to; but it does not appear that the ultimate result is such as to definitely and absolutely render it possible to recognise and detect adulterations of oils. The test is only of a relative value.

Extract from a Report on a New Process of the Quantitative Estimation of Quinine in Barks.—Dr. Carles.—The editors of this periodical state, in a foot-note, that they will shortly publish the author's memoir in full.

Chemical and Therapeutical Researches on the Thermo-Mineral Water of the Solfatara at or near Pouzzoles (Herault, France).—S. de Luca.—One litre of this water contains, in grammes' weight—Sulphuric acid (calculated anhydrous), 1'473; chlorine, 0'0085; protoxide of iron, 0'1105; lime, 0'101; magnesia, 0'0225; potassa, 0'017; ammonia, 0'0135; alumina, 0'335; silica, 0'315; soda, manganese, arsenic, and organic matters, traces; water, 997'603. This water may be industrially applied for the manufacture of alum.

Test for Detecting the Presence of Guaiacum Resin among the Resin of Jalap.—Dr. Blacher.—The author puts 50 centigrams of guaiacum resin, and 20 centigrams of oxide of copper, in a porcelain mortar, and adds about 20 drops of alcohol. When this mixture is triturated, nothing particular is seen, but, as soon as about 15 drops of ammonia are added, a beautiful apple-green colouration is produced. When this experiment is repeated with resin of jalap, no such green colouration whatever is seen; the mixture remains brown-coloured.

Bulletin de l'Académie Impériale des Sciences de St. Petersburg, Vol. xiv, Nos. 5 and 6.

These numbers contain the following papers relating to chemistry and allied sciences:—

Influence of Heat upon the Elasticity of Caoutchouc.—J. Schmelwitzsch.—An algebraico-physical essay.

Derivatives of the Isocaproin Series.—A. Borodin.—This paper treats chiefly, and at great length, on the products of the oxidation of a new monatomic alcohol, $C_{10}H_{22}O$. The main product obtained by the author is an aldehyde, a liquid boiling at 147°, and not frozen even at -37°; sp. gr. at 0°, 0'82783; formula, $C_{10}H_{20}O$. The author further describes an acid, $C_{10}H_{18}O_4$, which combines with bases, forming salts. The acid is a liquid, boiling at 241'5; sp. gr. at 0°, 0'90956 insoluble in water, but soluble, in every proportion, in alcohol and ether.

Annalen der Physik und Chemie, von Poggenдорff, No. 5, 1870.

This number contains the following original papers and memoirs:—

Influence of the Ponderable Molecules on the Dispersion of Light, and on the Importance of the Constant Dispersion Formulae.—E. Ketteler.—The continuation and end of this lengthy memoir.

Sound Emitted by Heated Tubes, and the Vibrations of Air in Tubes of Various Shapes.—Dr. C. Sondhauss.

On Chromates.—C. Freese.—In this portion of his lengthy essay, the author describes the following salts:—Chromate of copper and potassa, $Cu_2K_2Cr_2O_7$ + 200 parts; normal chromate of zinc; basic chromate of zinc (containing, in 100 parts— ZnO , 54'12; CrO_3 , 10'81; water, 11'57); chromate of zinc and potassa—

chromate⁺ and basic chromate of cadmium; chromate and basic chromate of nickel, $Ni_2CrO_6 + 2H_2O + aq.$; chromate of cobalt; and chromate of protoxide of manganese.

Mechanical Force Exerted by Moving Masses of Gas.—Dr. L. Boltzmann.

Calculation of the Vibrations of a String of a Musical Instrument, as referred to its Resistance to Bending.—R. Hoppe.

Figures Produced by the Action of Acids upon Certain Substances (Etching), and on the Phenomena of Asterism in Crystals.—Dr. H. Baumhauer.—Illustrated by a series of engravings.

Velocity of Molecular Motion and of Sound in Gases.—E. Mulder.

Production of Standing (Stehender) Vibrations and Sound Figures in Elastic and Fluid Liquids by the Aid of Solid-Sounding Plates.—A. Kundt.

Elastic Vibrations.—Dr. J. J. Müller.

Occurrence of Augite in Meteorites.—C. Rammelsberg.—This paper contains the following sections:—Enstatite in meteorites; bronzite in meteorites; augite in meteorites.

The Lodran Meteorite.—G. Tschermak.—The author found this meteorite to consist, in 100 parts, of:—Iron, 85.44; nickel, 12.70; magnesia, 0.81. Mineralogically, the stone consists of:—Nickeliferous iron, 32.5; olivine, 28.9; bronzite, anorthite, and chromite, 30.2; magnetic pyrites, 7.4 per cent.

Acoustical Attraction and Repulsion.—Dr. Schellbach.

Maximum Degree of Density and the Freezing-Point of Mixtures of Alcohol and Water.—Dr. F. Rossetti.

Beat Method for Studying the Nature of Flames.—L. Dufour.—The author describes a contrivance by means of which the well-known use of a wire gauze for examining the nature of flame is replaced by a thin sheet of water.

Colours Exhibited by Iodine.—C. Schultz-Sellack.—This paper treats chiefly on the differences exhibited by the colour of iodine in thin plates, in vapour, and in solution. Iodine is deep brownish red-coloured in thin layers; its vapour is violet; and some of its solutions exhibit the former, some the latter colour.

Platinum in Lapland.—Dr. Nordenskiöld.—It appears that gold having been found some years ago in the neighbourhood of the Ivalo river (Northerly Sweden), a more recent search there has given rise to the discovery also of some platinum, which, according to a brief foot-note added to this paper, has also recently been found near Ibbenhöhen, Westphalia.

Confirmative Test of the Genuineness of the Bohemian Diamond from Dlaschkowitz.—A few milligrams of this stone have been burnt in oxygen by Dr. Schafarik, in the presence of MM. Krejci, Rochleder, Waltenhofer, Zenger, and von Zepharovich. The result is that carbonic acid was given off, as proved by the turbidity caused by the products of combustion being led into baryta water, and no residue whatever being left.

The American Journal of Science and Arts, July, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Photometric Experiments.—Part II.

Amount of Light Transmitted by Plates of Polished Crown-Glass at a Perpendicular Incidence.—O. N. Rood.

The Ethers of Arsenic and of Arsenious Acid.—J. M. Crafts.—The author describes—Arseniate of ethyl, prepared by the action of the iodide of ethyl on the arseniate of silver. Arseniate of ethyl is a liquid; sp. gr. at 0°, 1.3204; it is a very unstable compound, which attracts moisture from the air, and is immediately decomposed into arsenic acid and alcohol; this body contains 33.18 per cent of arsenic. Arseniate of methyl, a liquid; sp. gr. at 15°, 1.5591. Arseniate of amyl. Arseniate of ethyl, also a liquid; sp. gr. 1.224; vapour density, 7.2673; this liquid is miscible with alcohol and ether, but is decomposed by aqueous alcohol. Arseniate of methyl: sp. gr. 1.428; vapour density, 5.828. Arsenite of amyl: sp. gr. 1.0525; this, and all the compounds alluded to, are not at all stable, being readily decomposed by water and moisture.

Notice of some Minerals from New Jersey.—W. T. Roepper.—The author describes, at some length—Chrysotile, a mineral containing chiefly iron, manganese, zinc, and silica, the percentage composition being:—Silica, 30.76; protoxide of iron, 33.78; protoxide of manganese, 16.25; oxide of zinc, 10.96; magnesia, 7.60. Magnesians dolomite, composed, in 100 parts, of:—Carbonate of lime, 50.40; carbonate of protoxide of manganese, 43.54; carbonate of protoxide of iron, 0.76; carbonate of magnesia, 5.69; insoluble, 0.08.

Miscellaneous Optical Notices.—Dr. Wolcott Gibbs.

Theoretical Temperature of the Sun, under the Hypothesis of a Gaseous Mass Maintaining its Volume by its Internal Heat, and Depending on the Laws of Gases as known to Terrestrial Experiment.—J. Homer Lane.

Mineralogical Contributions.—C. U. Shepard, sen.—The author describes, at length—A new variety of columbite, found to consist, in 100 parts, of:—Metallic acid, 78.30; protoxide of iron, 13.86; protoxide of manganese, 7.72; traces of tin. Unknown mineral (microlite?) in Haddam columbite. New locality of bismuthine and bismuthite, in Haddam. Metallic acid in microlite. Redondite, a mineral found in Redonda Island, and containing 41.07 per cent of phosphoric acid, 24.73 per cent of water, and oxide of iron and alumina. Phosphoric acid in the diaspor of Chester, Mass.; the mineral here alluded to is mainly hydrate of alumina, containing only 0.32 per cent of phosphoric acid. The Pelham vermiculite contains, in 100 parts—Alumina, 14.0; magnesia, 13.68; peroxide of iron, 32.0; silica, 24.0.

Hydrogenium-Amalgam.—O. Loew.

Journal für Praktische Chemie (double number), Nos. 11 and 12, 1870.

This number contains the following original memoirs:—

Foundation of Chemistry by Lavoisier.—J. Volhard.—This valuable memoir opens, unfortunately, with an attack upon the French as a nation, by stating that they are in the habit of very greatly exaggerating the merits of their great men, and, by so doing, forgetting the real value of their labours. The author's memoir is otherwise an excellent contribution to the early history of chemistry as a science, due stress being laid upon the high value of the labours of Scheele (a Swede), Priestley, Cavendish, Black, Marggraf, Fourcroy, Vauquelin, and others.

Quantitative Estimation and Separation of Cobalt and Nickel.—Dr. E. Fleischer.—To the acid solution of both metals, the author first adds hypochlorite of soda (eau de Javelle) and solution of caustic potassa in excess; the liquid is next heated to the boiling-point; and the ebullition is continued until the precipitate has become quite black. The precipitate is collected on a filter. The mixed sesquioxides are separated from each other by the use of warm liquid ammonia, which dissolves the sesquioxide of nickel, leaving the sesquioxide of cobalt.

Action of Chloride of Chromic Acid upon Aromatic Hydrocarbons.—E. Carstangen.—This lengthy memoir is divided into the following sections:—Introduction; action of chloride of chromic acid upon naphthalene, anthracene, toluol, xylol, mesitylene, diphenyl, phenol, nitrobenzol, aniline.

Crystalline Pigment of Turmeric Root.—Dr. F. W. Daube.—This paper has been already alluded to, having been abstracted from another German periodical (see *CHEMICAL NEWS*, vol. xxii, p. 84); but the paper, as published in the above-named periodical, contains, besides, the following brief notice relating to the essential oil of turmeric root:—Forty pounds of the Bengal root yielded, when treated with steam, 400 grms. (about 2 per cent) of the essential oil, which is to be further investigated by Dr. Claus.

Revue des Cours Scientifiques de la France et de l'Etranger, July 23, 1870.

This number does not contain any original papers relating to chemistry or collateral sciences, but we learn that Professor Helmholtz, appointed to succeed the late Professor Magnus, at Berlin, will not leave for that place until the month of April next, it being his desire to stay the winter at Heidelberg.

Condensing Hydrochloric Acid Gas.—(Reply to "Salt").—Consult Richardson and Watts's "Chemical Technology," vol. i., part 3.

Brewing Queries.—(Reply to T. Gregson).—Consult "Theory and Practice of Brewing," by W. L. Tizard (London, 1854), which you can inspect at the Library of the Commissioners of Patents.

Estimation of Alkalies in Silicates.—"Analyst" will find a full description of Dr. Lawrence Smith's method of estimating the alkalies in silicates in my "Manual of Chemical Analysis," p. 473. I have been using this method rather extensively lately in the analyses of fire-clays and bricks, and can recommend it as both simple and accurate. I mix 50 grains of the clay or brick with 250 grains of carbonate of calcium and 30 grains of chloride of ammonium, and heat to bright redness in a platinum crucible for half an hour; neither fusion nor a higher temperature than bright redness are necessary. I obtain the carbonate of calcium pure, by precipitating pure chloride of calcium by carbonate of ammonium; neither carbonate of sodium nor carbonate of potassium must be used, it being impossible to free the precipitated carbonate of calcium from either of these alkalies by any amount of washing. To prove this, I may mention that, having found in a sample of carbonate of calcium, which had been precipitated by carbonate of sodium, nearly 1 per cent of carbonate of sodium, I washed it almost uninterruptedly for several days with boiling distilled water, but failed to remove any material quantity of the alkali.—HENRY M. NOAD, St. George's Hospital.

TO CORRESPONDENTS.

* Vol. XXI. of THE CHEMICAL NEWS, containing a copious index is now ready, price 11s. 4d., by post, 11s. 10d., handsomely bound in cloth, gold-lettered. The cases for binding may be obtained at our office, price 1s. 6d. Subscribers may have their copies bound for 2s. 6d. if sent to our office, or, if accompanied by a cloth case, for 1s. Subscribers wishing to complete their sets of volumes are requested to apply to the publisher, who will give them information respecting scarce numbers and volumes. Vol. xxii. commenced on July 1st, and will be complete in twenty-six numbers.

NUCLEI AND SUPERSATURATED SALINE SOLUTIONS.

By ARCHIBALD LIVERSIDGE,
Associate of the Royal School of Mines.

PROFESSOR TYNDALL has shown, by means of the beam from an electric lamp, that the minute particles of dust which ever float in the disturbed air, may be effectually arrested by means of a cotton wool filter; he therefore recommends (*Nature*, vol. i., p. 342) the use of cotton wool respirators as a defence against contagion, since they would completely intercept the dirt and germs borne by the atmosphere.

In order to ascertain if there were any real necessity for such respirators—in fact, to prove the filtering power of our natural respirator, the nose—the following experiment was performed:—

Expt.—A flask containing a supersaturated solution of sodic sulphate was fitted up as a Woulff's bottle; whilst the solution was cooling the apertures of the two tubes were plugged with cotton wool. When the solution was cold these plugs were withdrawn, and air which had been respired through the nose was forced through the solution.

In some cases the current of air was maintained for ten or fifteen minutes. The solution was kept cold by the immersion of the flask in water, for if the temperature had been allowed to rise by the absorption of heat from the breath the experiment, would, of course, have been vitiated.

No effect was produced, thus showing the perfect efficiency of the hairs and mucous membranes lining the nasal passages in arresting nuclei.

When we inspire through the mouth, the dust of the air has a free and unimpeded course to the lungs, where it settles and clogs up the delicate air passages with putrescent matter. Not only is the air purified by inhaling it through the proper channel, but it is warmed also.*

In an abstract of one of his papers (*CHEMICAL NEWS*, vol. xix., p. 128) Mr. Tomlinson explained the sense in which he applied the term catharism or "chemical cleanness" in contradistinction to ordinary cleanness, by stating that the finger could not possibly be made clean (*i.e.*, inactive as a nucleus) by any process, whereas a glass rod could be.

Regarding the finger as a greasy rod, I could see no reason why it should not be made inactive in the same way as a glass or other rod.

Expt.—Held the finger in water for a minute or so, then transferred it to the supersaturated solution. No effect.

Expt.—Passed the finger through a spirit-lamp flame several times, then immersed it in the solution. No effect.

Hence, the finger is readily made to behave as if it were catharised.

In the last number of the *CHEMICAL NEWS* (p. 88), Mr. Tomlinson states that oil and fatty bodies, whether chemically clean or not, do not act when in mass, as globules, &c., but only in thin films.

For my part, I have never found that the quantity or form of the oil, &c., has ever had any effect upon the behaviour of the salt in solution. Many times the oil or fat has been spread over the surface of the solution as a thin film, even thin enough to be iridescent, and the

internal surface of the flask has also been coated in the same way, but this has not determined the solidification of the salt.

Then again, on the same page, he says, oils and fats are chemically clean which are chemically pure. Does not the following refute this statement?

Expt.—A mixture of wax, oil, soot, dust from floor, sulphur, sodic sulphate, soap, &c., was melted together on a glass rod and then dipped into the supersaturated solution. No effect.

The oil and fat in this case were certainly not chemically pure; therefore, according to Mr. Tomlinson, they ought not to have been chemically clean, *i.e.* inactive; but they were inactive nevertheless.

Might I suggest that it would, perhaps, be as well to do away with the terms "chemically clean" and "catharism," for if my results be trustworthy—and I have been at much pains to make them so—the conclusion to be derived from them is that there is no connection whatever between the active state of a nucleus and its want of chemical purity; a pure chemical or other pure body is just as quickly rendered active as a nucleus by exposure to the air or by contact with objects which have been so exposed, as is a substance composed of the most heterogeneous mixture imaginable,* and they may both, with equal facility, be re-converted into the inactive state on exposure to a sufficient heat or to moisture.

Although in my former paper I suggested, and do still, that nuclei may be found to consist of microscopic organisms, I do not quite reject M. Gerné's hypothesis that the nuclei may consist of universally diffused particles of the sodic sulphate, but in what state it exists and exerts its influence has not yet been shown. Mr. Tomlinson has pointed out that it is not in the form of the anhydrous salt, nor is it that with seven atoms of water, since you obtain both these salts nearly every time you prepare a supersaturated solution; and ignited sodic sulphate is certainly not a nucleus. All we can do is to still apply questions and extort an answer from nature.

London, August 19th, 1870.

ON THE FUNCTIONS OF NUCLEI WITH RESPECT TO SUPERSATURATED SALINE SOLUTIONS.

By CHARLES TOMLINSON, F.R.S.

I TRUST it will not be thought disrespectful to fellow-workers in the same field, if I refer them to my paper on supersaturated solutions, which was read before the Royal Society on the 16th June last, an abstract of which is printed in the *Proceedings*, No. 122, page 533.

I think it will be found that the line of experimental research adopted by Mr. Grenfell, and also by Mr. Liversidge, had been anticipated by me; but it would afford me the highest satisfaction if such able observers would review their work with reference to my latest results.

It will be seen from my note, in answer to Mr. Grenfell, that my definition of *chemically clean* applies to all bodies, including oils and solid fats. If a stick of tallow be chemically clean it will not act as a nucleus, because the solution adheres to it as a whole; but a film of tallow will act powerfully. So, also, a globule of castor oil will not act if chemically clean, but a film of it will act as a nucleus.

If a drop of a liquid be placed on the surface of a supersaturated saline solution, it will (apart from chemical action) do one of three things; (1) it will diffuse through the liquid, and in general not act as a nucleus, as in the case of glycerin; (2) it will spread out into a film; or (3)

* There is nothing to prevent each of the constituents being itself chemically pure, and if each, when separate, is inactive, why should the mixture not be inactive also?

* See a letter upon this in *Nature* for Feb. 17, 1870.

remain in a lenticular form. It becomes a film or a lens according to the general proposition, that if on the surface of the liquid A, whose surface tension is a , we deposit a drop of the liquid B, whose surface tension, b , is less than a , the drop will spread into a film; but if, on the contrary, b be greater than a , or only a little less, the drop will remain as a lens. The *superficial viscosity* of the solution may in some cases interfere with the rigid application of this proposition.

An active, or non-catharised surface, is one contaminated with a film of foreign matter, the filmy condition appearing to be necessary to secure that close adhesion which brings about the nuclear action.

Some liquids, such as alcohol, form films and act as nuclei by separating water instead of salt from supersaturated solutions.

Fatty oils may saponify, or oil of bitter almonds form benzoic acid, in contact with supersaturated solutions of Glauber's salt without acting as nuclei.

When a drop of a fatty oil spreads out into a film on the surface of a cold supersaturated solution of Glauber's salt, very fine prismatic plates of the ten-atom salt, with dihedral summits, fall from every part of the lower surface of the film; an effect quite different from the crowded diverging mass of crystalline needles which proceeds from a point in the surface when a speck of dust is let in, or the surface is touched at one place.

Liquids such as ether, alcohol, naphtha, benzol, oil of turpentine, cajuput, and other volatile oils; sperm, herring, seal, olive, linseed, castor, and other fixed oils, act powerfully as nuclei when they form films; but when they form lenses there is no separation of salt, even though the flask, being whirled round, so as to break up the lens into small globules. But if, by a sudden jerk, a globule of oil be flattened into a film, the solution immediately becomes solid.

"Stearine from sheep's tallow that had been exposed to the air produced immediate crystallisation; but by boiling the solution, and covering the flasks, the stearine, now catharised, had lost its nuclear character in the cold solution. Similar observations were made with the fixed oils that form lenses or globules in the solution. So also volatile oils, containing products of oxidation, dust, &c., are nuclear, but when catharised, by being re-distilled, they are inactive in the globular state, active in the form of films.

"When a liquid forms a film on the surface of a supersaturated solution, the surface-tension of the solution is so far diminished as to bring the film into contact with the solution, when that differential kind of action takes place, whereby, the salt of the solution adhering more strongly to the film than the water of the solution, the action of separation and crystallisation, thus once begun, is propagated throughout. A similar action takes place with solid bodies that have contracted filmy nuclei, by being touched or drawn through the hand, or merely exposed to the air; they are active or nuclear by virtue of the films of matter which more or less cover them.

"On the other hand, when a drop of oil (or many drops) is placed on the surface of a supersaturated saline solution, and it assumes the lenticular form, or even flattens into a disc, such lens or disc is separated from actual contact with the solution, by surface tension. That the adhesion is very different from that of a film may be shown by pouring a quantity of recently distilled turpentine, for example, on the surface of chemically clean water, and scraping upon it some fragments of camphor; these will be immediately covered with a solution of camphor in the oil, which solution will form iridescent films, and sail about with the camphor, vigorously displacing the turpentine, and cutting it up into smaller discs and lenses. So in the case of supersaturated saline solutions, the oil-lens is not sufficiently in contact with the surface of the solution to allow of the exertion of that differential kind of action whereby salt is separated. Even when by shaking, the oil is broken up into globules,

and these are submerged, they are still so far separated from the solution by surface-tension as to prevent actual contact."

It should be remarked that, in experiments on the action of nuclei on supersaturated saline solutions, the flasks must on no account be plugged with cotton wool, because in removing the plug an equal volume of air enters, and is almost certain to carry active nuclei with it. The process adopted by me is to boil a solution of 1, 2, or 3 parts of Glauber's salt to 1 part of water in a large flask, and to filter the boiling solution into 6, 8, or 10 five or six ounce flasks (each flask receiving two or three ounces of the solution), and then, covering each with a watch glass, to leave the flasks until cold, or until the next day. If the solutions had previously been operated on with fixed oils, the flasks, although cleaned for fresh trials, may not be so clean but that strong solutions in cooling crystallise. This may in general be prevented by re-boiling the solution for a few seconds after it has been filtered into the small flasks. In making an experiment, thin fluids, such as ether, benzol, &c., may be taken up in a clean straight dropping tube, fatty oils on a clean glass rod, and the watch glass being gently removed, a drop of the liquid is to be deposited on the surface, the tube or rod to be slowly withdrawn, and the watch glass replaced. In shaking a flask, the watch glass is to be held down firmly with the finger or thumb of the hand that grasps the neck.

Sodic sulphate is the best salt for the class of experiments indicated, but I have obtained good results with supersaturated solutions of potash and of ammonia alum, of sodic acetate, and of magnesia sulphate. The films which spread on the solutions of alum produce very fine results of crystallisation.

Highgate, N., August 19th, 1870.

PRELIMINARY NOTICE ON THE NITRO-SUBSTITUTION COMPOUNDS OF THE ORCINS.

By J. STENHOUSE, LL.D., F.R.S., &c.

MANY attempts have been made to prepare a nitro-compound from orcin, but hitherto without success—the orcin being converted, by strong nitric acid at ordinary temperatures, into resinous uncrystallisable compounds. When, however, colourless orcin in fine powder is gradually added to strong nitric acid cooled by a freezing mixture, it dissolves, with a pale brown colouration, but without the slightest evolution of nitrous fumes. If this solution be now slowly dropped into concentrated sulphuric acid cooled to a low temperature, the mixture becomes yellow and pasty, from the formation of the nitro-orcin, which is but slightly soluble in sulphuric acid. This is now poured into a considerable quantity of cold water, when the nitro body separates as a bright yellow crystalline powder, without any admixture of resin. One or two crystallisations from boiling-water suffice to render it quite pure. It is thus obtained in large yellow needles, which are soluble in alcohol, slightly soluble in cold water, but readily in hot. On analysis, it was found to have the composition corresponding to the formula—

that of trinitro-orcin. It is a powerful acid, much resembling picric acid, but distinguished from the latter by the solubility of its salts; I therefore propose to call this new substance *trinitro-orcinic acid*.

Trinitro-orcinic acid of Potassium.—This is readily prepared from trinitro-orcinic acid, by dissolving it in a warm and rather concentrated solution of potassic carbonate. On cooling, it solidifies to a crystalline mass of fine needles

of a deep orange colour. The salt, dried at 100° C., has the composition—

The sodium-, calcium-, and silver-salts of this acid all crystallise well, and are tolerably soluble in water; the lead-salt is much less soluble.

Trinitro-resorcinic Acid.—Resorcin, prepared from galbanum by the excellent method given by its discoverers, Hlasiwicz and Barth, was treated with nitric and sulphuric acids, in precisely the same manner as that above described for orcin, and with similar results. Trinitro-resorcinic acid, when pure, crystallises readily, but is of a much paler colour than trinitro-orcinic acid, which it closely resembles in most of its properties. Analyses of the substance showed its composition to be $\text{C}_6\text{H}_3(\text{NO}_2)_3\text{O}_2$. It readily forms crystalline salts.

Trinitro-betaorcinic Acid.—Betaorcin, $\text{C}_8\text{H}_{10}\text{O}_2$, when treated with nitric and sulphuric acids as above described, gives a yellow substance, which appears to be the corresponding nitro compound of betaorcin; but, from the small amount of material at my disposal, I am at present unable to accurately determine its properties.

From some experiments I have made, the action of reducing agents, nitrous acid, &c., upon the nitro-compounds promise very interesting results; these, together with the preceding compounds, I am at present investigating.

The Laboratory, Rodney Street, Pentonville,
August 23rd, 1870.

EXAMPLES FOR PRACTICE IN QUANTITATIVE CHEMICAL ANALYSIS.*

By FRANK H. STORER,
Professor in Massachusetts Institute of Technology.

(Continued from p. 90).

EXPERIMENT II.—Determination of Water and Sulphuric Acid in Gypsum.

To estimate the water, weigh out about 7 grms. of the finely-powdered mineral in a porcelain crucible of known weight. Heat the crucible over a Bunsen burner, at first gently, but afterward strongly. Allow the crucible to cool, and weigh it with its contents; again heat, cool, and weigh, and repeat these operations until the weight remains constant. Half an hour will be time enough for the whole work. The total loss of weight represents the water which the mineral contained. In our experiment 7.043 grms. of transparent, crystallised gypsum (*selenite*) lost 1.48 grms.

$$7.043 : 1.48 = 100 : 21.01 \text{ per cent.}$$

For the formula $\text{CaSO}_4 + 2\text{H}_2\text{O}$, theory requires 20.93 per cent of water.

To determine the sulphuric acid, transfer the ignited mineral in which the water has been determined from the crucible to a beaker of 600 or 700 c.c. capacity, pour upon it 100 c.c. of dilute chlorhydric acid (free from sulphuric acid), prepared by mixing 2 parts of water with 1 part of the strong acid. Heat the mixture twenty or thirty minutes, or until the gypsum has all disappeared. Pour in water enough to half fill the beaker, heat the solution nearly to boiling, and add to it a solution of chloride of barium, little by little, as long as any precipitate continues to fall. Stir the liquid continually with a glass rod while adding the chloride of barium, and during the subsequent heating, in order that no "bumping" may occur. After enough chloride of barium has been added, keep the liquor hot for five or ten minutes, then set it aside for ten or twelve hours in a moderately warm place, in order that the

particles of sulphate of barium may subside, and become somewhat compacted and coherent.

Pour the clear supernatant liquor upon a six-inch filter, wash the precipitate in the beaker by decantation, first with boiling water, then with a boiling solution of acetate of ammonium (to decompose and remove any chloride of barium which may have been dragged down in combination with the sulphate), and, finally, three or four times with boiling water. Then transfer the precipitate from the beaker to the filter, pour hot water upon it until all the chloride of calcium has been removed, so that a drop of the filtrate, carefully evaporated to dryness upon a slip of glass, leaves no residue. Dry, ignite, and weigh, as in the preceding experiment.

$$\begin{array}{l} \text{Molec. wt. of BaO,SO}_3 : \text{Molec. wt. of SO}_3 = \text{The wt. of BaO,SO}_3 : \text{Wt. of SO}_3 \\ \text{of SO}_3 \qquad \qquad \qquad \text{found} \qquad \qquad \text{therein.} \end{array}$$

From the aforesaid 7.043 grms. of mineral, there was obtained 9.5545 grms. of BaO,SO_3 (= 3.28 grms. SO_3).

$$7.043 : 3.28 = 100 : 46.57 \text{ per cent.}$$

Theory requires 46.51 per cent.

The percentage amount of oxide of calcium contained in the mineral was estimated "by the difference." $100 - (21.01 + 46.57) = 32.42$. Theory requires 32.56. The result of the analysis may be tabulated as follows:—

	Found.	Theory.
CaO (by difference) ..	32.42	32.56
SO ₃	46.57	46.51
2H ₂ O	21.01	20.93
	100.00	100.00

(To be continued.)

ON THE PREPARATION OF SPECIMENS OF SOUNDINGS FOR THE MICROSCOPE.*

By Professor A. M. EDWARDS.

In the course of his gatherings it not unfrequently happens that the microscopist acquires specimens of the bottom of the ocean, from various localities, which, if properly prepared, furnish him with many beautiful objects for observation and study. And the beauty of these objects, the remains of once-living organisms, are of such a marked character and present so many points for admiration that, even to the unscientific observer, they become sources of pleasure often leading to farther enquiry into their life-history, so that imperceptibly almost, and by gradual degrees, the possessor becomes a student, in fact, and is induced to follow up his investigations to some practical end.

At the present time such specimens are of special interest, on account of the remarkable revelations made by the deep-sea dredging, lately carried on upon our coast and in Europe, and the bearing of these specimens upon Geology, Zoology, as well as other branches of science. The immense tracts covered by what Dr. Carpenter has characteristically termed "Globigerina-mud," on account of it teeming with *Foraminifera* so called and the connection of Prof. Huxley's "Coccoliths and Coccospheres," with the formation of the chalk-beds of the Cretaceous, open up to the microscopists an universe of new facts for investigation. Added to these calcareous organisms, the specimens of sea-bottom presents us with siliceous forms, both animal and vegetable, of surprising delicacy and beauty of outline and structure, and it was to these last named that my attention has been more particularly turned.

* Communicated by the Author. From the Massachusetts Teacher.

* From the Proceedings of the Lyceum of Natural History, New York.

Among such specimens of sea-bottom, the soundings taken at different times, and at various points on the coast of the United States by the Coast Survey, have been subjects of extreme value to the scientific observer, while they have, at the same time, furnished many unscientific possessors of microscopes with matter for admiration, wonderment, and joy; the graceful *Diatomacea*, the symmetrical *Radiolaria*, and marvellous *Foraminifera*, often present in such profusion, serving to enable the preparer to put up slides of surpassing beauty.

One of these soundings, for which I am indebted to the Smithsonian Institution, was of such a character that I was extremely desirous of studying as completely as possible the forms presented in it, belonging, as they did, to all of the three families mentioned, besides which it contained several minute mollusca and the remains of sponges and other organisms. It was, as shown by the remains present, of such a character as to consist essentially of calcium carbonate, commonly known as carbonate of lime, and silicon dioxide (silica), built up into the skeletons of dead organisms. The problem, then, presented to me, was to prepare it in such a way, if possible, first, to show all of these objects at the same time, or, second, to separate it into calcareous and siliceous specimens, and this last method I found, after trial, to be the best. As my mode of manipulation may hereafter be of value to others possessing similar gatherings, I will give it in detail.

The sounding, being in the shape of a dry powder of a light greyish-green colour, was placed in a suitable glass vessel and moderately strong liquor potassa poured upon it. It was now boiled for a few moments, until I saw that the lumps present in it were broken up, and a light mud-like sediment was the result. The solution of potassa must be, of course, apportioned in strength to the specimen under manipulation; such as consists of many lumps and much organic matter will require it of greater strength than that which is mostly calcareous and siliceous. If it be used too strong, some of the more delicate siliceous forms will be attacked, or even, as I have occasionally found, entirely dissolved. After it had boiled for a short time, as I have said, I allowed it to stand until the mud had settled, and a tolerably clear solution was left above it. I now poured off most of the liquor potassa, and replaced it by a strong solution of chloride of soda, so-called. That sold by apothecaries under the name of "Labarraque's solution" will answer generally, and is readily procured. This I now boiled until I found its action to cease. By this means the mud is so much bleached as to become almost white. The potassa, at first, has the effect of dissolving much of the organic matter present, and thus breaking up the lumps and setting the shells free, and the chloride of soda solution bleaches them, so that we have them clean and separated to such an extent that, under the microscope, the individual shells are easily recognised. I now proceeded to separate the larger from the smaller forms by means of the "elutriation" process, which consists in first washing off thoroughly all the potassa and chloride of soda with pure filtered or distilled water, and shaking up the sediment in a glass about two inches high filled also with water. If now permitted to stand for a few seconds, the larger forms and coarser sand settles, and the supernatant liquid can be poured off into another larger vessel. Again, water is added to the first sediment, and, in turn, removed, and this is done as many as six or eight times, until we see that the coarse sediment is not contaminated by finer particles by the water it is shaken in remaining almost clear. The same process is carried out with the sediment in the second vessel, only permitting each charge of water to stand longer than in the first case, as the forms are now much smaller and require longer to settle. In this way we may get three or four densities of sediment, although I found that my specimen yielded but two which contained anything of interest of a calcareous nature. After, then, setting aside the two first sediments, I carefully acted upon

what was left with hydrogen nitrate (nitric acid), and procured a small quantity of a sediment, consisting, for the most part, of nothing but the siliceous lorica of *Diatomacea*. They were very few, however; so, to procure all the remains of *Diatomacea* and other siliceous organisms present in the gathering, I took a quantity in the rough state, and, after breaking it down by potassa, acted on it with boiling hydrogen nitrate. Thus I found that I had good representatives of all the gathering contained. Some specimens, however, are not thoroughly cleaned by boiling, even for a considerable length of time in strong hydrogen nitrate. To such I add either hydrogen chloride alone or a few grains of finely-pulverised potassium dichromate. In this way, and after thoroughly washing with pure water, I have been enabled to obtain extremely beautiful specimens of *Diatomacea*, *Radiolaria*, and other siliceous organisms in a good condition for studying them. This I am engaged upon at the present time, and intend, before long, to lay the results before the Lyceum.

ON THE ANILINE OR COAL-TAR COLOURS.*

By W. H. PERKIN, F.R.S.

(Concluded from p. 93.)

I HAVE in these lectures brought before you, in a rapid—
—I fear too rapid—manner, an account of most of the coal-tar colours; but, before concluding, I should like to show you the close relationship which exists between some of them, especially between those derived from rosaniline or magenta.

I have endeavoured to show you that the derivatives of magenta closely agree in properties, all of them containing colourless organic bases, the colour being developed upon their combining with acids. But I now wish to show you more than this; by briefly explaining their chemical structure. To describe this thoroughly, it would be necessary for me to enter fully into the chemical theory of substitution; but, as this would occupy a great deal of time, I must content myself with just mentioning a few facts connected with that subject.

Rosaniline and its derivatives contain carbon, hydrogen, and nitrogen, as I have told you on a previous occasion. Chemical substances containing hydrogen often hold it in what is termed a replaceable condition—that is, in such a condition that it may easily be removed—and another substance of equal value (either simple or compound) introduced in its place. A compound substance capable of replacing hydrogen is called a "radical"; and I want to speak about two of these radicals, one called ethyl, and contained in iodide of ethyl, the other called phenyl, and contained in aniline.

Ethyl contains C_2H_5 .
Phenyl " C_6H_5 .

I will first mention a familiar instance of the replacement of hydrogen by a radical. Water is composed of two equivalents of hydrogen and one of oxygen, thus—

Now, it is quite easy to remove an equivalent of this hydrogen and replace it by ethyl.

This is water with hydrogen replaced by ethyl, a replacement compound by some very much preferred to water itself; it is alcohol.

* The Cantor lectures, delivered before the Society of Arts.

Rosaniline contains three equivalents of hydrogen, replaceable by radicals. This is the formula of the hydrochlorate of rosaniline, the three separate H's being replaceable:—

Now, what takes place upon boiling this salt with aniline? The phenyl of the aniline simply takes the place of the replaceable hydrogen, producing what is called triphenyl-rostaniline. The result of this replacement is that the rosaniline salt has been changed from red into blue—the bleu de Lyon—which is represented thus:—

Dr. Hofmann, on observing this relationship, was induced to try whether he could replace the hydrogen in rosaniline by other radicals than phenyl. He tried to introduce ethyl by digesting rosaniline with iodide of ethyl, and succeeded in introducing three molecules of the radical ethyl in the place of the three replaceable hydrogens. I will endeavour to show you how this takes place, by the following equation:—

Here we see the iodine has simply exchanged its ethyl for the replaceable hydrogen of rosaniline, and the result is a blue shade of the Hofmann violet.

Now it is not necessary to replace the three hydrogens; two may be replaced, and we get a less blue violet, represented thus

Or, one may be replaced, and we get a red-violet, represented thus—

When speaking of the violet imperial, I mentioned that it consisted of products intermediate between rosaniline and the bleu de Lyon. These intermediate substances consist of rosaniline with one or two equivalents of hydrogen replaced by phenyl.

Up to the present moment, it has only been found possible to replace one equivalent of hydrogen in mauveine, or the mauve dye; and, as I previously mentioned, it is curious that the result of this replacement is perfectly opposite to that which takes place in the case of rosaniline, the replacement of hydrogen by ethyl in rosaniline causing it to become bluer in shade, and the replacement of hydrogen by ethyl in mauveine causing it

to become redder in shade. The following is the formula of the hydrochlorate of ethyl-mauveine or dahlia:—

But, although I have tried to explain the relationship of these colouring matters as simply as I can, yet this part of my lecture assumes much of the character of a lecture on theoretical chemistry. Here we are talking about substitution products of bodies, a branch of the highest theoretical chemistry, and it must strike us as remarkable, when we find that these considerations have been pressed upon us by the discussion of bodies which may now be said to be common dye-stuffs. We have also been talking quite in a familiar manner about nitrobenzol, aniline, iodide of ethyl, aldehyde, &c., substances which were, only a few years since, the *recherché* compounds of the laboratory. In fact, the coal-tar colour industry is entirely the fruit of theoretical chemistry. Let us consider the enormous rapidity with which this industry has developed. It only dates from 1856, and now we have large factories for the production of coal-tar colours, not only in Great Britain, but in Germany, France, Switzerland, America, and other countries. I had hoped to have been able to give you a statistical account of this industry, but have not had sufficient time for this purpose. Dr. Hofmann, however, in his report on the coal-tar colours shown at the Paris Exhibition of 1867, remarks that, "in 1862, the value of these manufactures had risen from nothing to 10,000,000 of francs, or more than £400,000 sterling. At the present day this sum is trebled, which would make it about one million and a quarter pounds sterling, although the products are much cheaper than they were before." And now, when you hear of these results, do not forget that they are the truly practical fruits of theoretical chemistry, not studied for the purpose of producing commercial products, but simply for its own sake.

THE DETERMINATION OF COMBINED CARBON IN IRON AND STEEL BY THE CCLORIMETRIC PROCESS.*

By J. BLODGET BRITTON,
Of the Iron-Masters' Laboratory.

LONG ago Professor Eggertz, of Fahlun, Sweden, called the attention of metallurgical chemists to the fact that when pure metallic iron is dissolved in nitric acid, of common strength, the solution, if not too concentrated, is colourless, or nearly so; but when steel, or iron containing carbon in combination, is substituted for the pure metal, the solution is coloured, and the shade varies exactly in proportion to the amount of carbon present; and, based upon this fact, he suggested a method whereby carbon determinations, sufficiently accurate for many commercial purposes, could be made with facility.

Several modifications of this method have been proposed. One of them, affording exceedingly accurate results, has been in use at the Iron-Masters' Laboratory for some time. Instead of a single tube, containing a standard solution for comparison, as suggested by Eggertz, a number of tubes having their solutions differently standardised, one from the other, are employed. These are arranged securely in a walnut-wood frame, with spaces between for placing the tube containing the solution to be tested, and forming together a convenient portable instrument called a colorimeter—an exact representation of such an instrument is here annexed. The position of the tube containing the solution to be tested is shown at A.

* Communicated by Professor Morton. From advance-sheets of the *Journal of the Franklin Institute*.

The tubes are $\frac{1}{8}$ ths of an inch in diameter, and $3\frac{1}{4}$ inches in length, filled with water and alcohol coloured with roasted coffee, and hermetically sealed. The solution in the tube to the left has its colour to correspond exactly with one produced by 1 gm. of iron, containing 0.02 per cent of combined carbon, dissolved in 15 c.c. of nitric acid. The solution in the tube next to it has its colour to correspond with one produced by the same quantity of iron, but containing 0.04 per cent of combined carbon, and so with each of the other tubes, increasing 0.02 per cent of carbon in regular succession to the right, the last reaching 0.3 per cent as indicated by the figures on the upper rail of the instrument.

On the back of the instrument, and for the purpose of partially screening the light and allowing the different shades of colour to be distinctly discerned, there is tightly stretched between the rails some fine white parchment paper. This screen is not shown by the cut, but it serves a very important purpose.

The process is conducted as follows:—1 gm. of the finely divided metal is put into a tube of about $1\frac{1}{4}$ inches in diameter and 10 inches long, and digested for fifteen or twenty minutes in 10 c.c. of nitric acid of a little more than 1.20 sp. gr. free from chlorine. The solution is then cautiously poured into a beaker, and a small portion of metal which remains undissolved and adheres to the bottom of the tube, is treated with 5 c.c. of fresh acid and exposed to a gentle heat till completely dissolved and added to the other. The contents of the beaker, when sufficiently cool, are filtered through two thicknesses of German paper (not previously moistened and of a diameter not exceeding $\frac{1}{4}$ inches) into a tube about 5 inches long

and of precisely the same diameter as those in the instrument.

After the filtered solution has remained for some minutes, at the temperature of the atmosphere, and its colour become fixed, the tube is placed in the instrument and the carbon determined by a comparison of shades;—the determination may be made readily as close as 0.01 per cent.

Heat should not be applied in the first instance to facilitate the solution of the metal, because a high temperature is apt to cause a slight loss of colour. Two thicknesses of paper are taken because one alone is liable to break; and the paper should be used dry, for, if previously wetted, the water will weaken the colour of the solution, and it ought to be cut to a size not exceeding $\frac{1}{4}$ inches to prevent undue absorption.

If the metal to be examined contains more than 30 per cent of carbon, 0.5 gm. or less of it, may be taken, or the solution may be diluted with an equal volume or more of water and the proper allowance made; or an instrument of higher range may be used. On the other hand, if the metal contains a very small per cent of carbon, 2 grms. of it may be taken. For preparing the standard solutions (the normal ones begin to lose colour after some hours), caramel dissolved in equal parts of water and alcohol, as suggested by Eggertz, answers well; but with roasted coffee as the colouring matter I have succeeded in obtaining the true shades. I must say, however, that this latter solution has not been in use sufficiently long to allow me to positively assert that its colour will not change after some length of time. As a rule, the instruments are kept in the dark, except when in actual use, and no perceptible change has yet taken place.

ON THE TEMPERATURE AND HEATING-POWERS OF FLAMES.

By Professor H. WURTZ.

In the *CHEMICAL NEWS* of June 24, there is a communication (said to be copied from the *Philosophical Magazine*, which latter I have not yet seen), with criticisms by W. M. Watts, D.Sc., upon the paper of Professor Silliman and myself on the "Calorific Powers or Effects of Gases," read to the American Association at Salem in August of last year, as forming the introductory part of a pending investigation on the important practical subject of the temperatures of the flames of such gases as are ordinarily employed for heating and lighting purposes. This paper was published in the previous issue of the *CHEMICAL NEWS*.

Mr. Watts accuses us, first, of "confusion" between heating-powers and flame-temperatures, not observing that this introductory paper is confined to heating-powers or effects, the subject of temperatures being left to future occasions; hence he betrays inattention to our paper, if not confusion of ideas on his own part, when he suggests to us, in a note, that in our first conclusion on the heating effect of carbonic oxide, we really mean the "flame-temperature" thereof. Such a change in our wording would be confusion indeed. The temperature of an open flame is usually highly variable in various parts, and we have applied the term "flame-temperature" to that of the hottest zone only. I believe that to any attentive reader, not anxious to pick flaws, our meaning in the use of the term maximum calorific effect must be manifest; namely, the total and final amount of heat (so to speak) or heating result, after total combustion, without regard to time or rapidity of combustion, of which, of course, the temperature is a function.

Mr. Watts's reasoning against our result as to the heating effect (called by him flame-temperature) of elefant gas being lower than that of carbonic oxide, especially compels me to think that he has not read our paper with that attention which so confident a criticism should imply. This reasoning may apply, partially at least, to the case of the combustion of these two gases with the necessary amount of pure oxygen, being then essentially a re-statement (though not complete) of the conditions of the actual experiments of Favre and Silbermann, but is wide of any application to our own case, in which the nitrogen of the air plays a large part. In burning in the air, as a simple calculation shows, one volume of CO has to heat but two volumes of N and half a volume of O, whereas one volume of elefant has to heat more than 11 (exactly 11.29) volumes of N and three volumes of O, or 14.29 volumes altogether, up to the temperature of its flame, or of the body heated thereby. Thus in the case of aerial combustion, the total heat of the elefant volume is distributed or divided throughout 5.72 times greater bulk of air than is the case with carbonic oxide. Hence (in part) the lower calorific effect of elefant in air, even when the latent heat of the steam of combustion is recovered by condensation. Of these, with other things, Mr. Watts takes no heed, and, in view thereof, I think that we can justly retort his accusation of "confusion."

As to the correction necessary in Bunsen's gasometry, for the heat of the steam of combustion of hydrogen, we were informed that this had been made, but not by whom. Our informant, Professor Cooke, of Cambridge, thought by Bunsen himself, but we were unable to verify this, and in a note to our paper, as published in the *American Journal of Science* (p. 342) referred to the subject somewhat doubtfully. Our thanks are therefore due to Mr. Watts for the reference to Dibbitts.

The exception made by Mr. Watts to the formula

for the total calorific of hydrogen relating to the correction for the difference between the specific heats of water and steam, is one which I cannot at present individually enter upon, and to which I shall again return. I will merely say that there has been controversy upon the points here involved; mentioning, also, that the number calculated by Deville, for the total calorific power of hydrogen in oxygen is 6800°, which is about the mean between Mr. Watts, and the figure adopted by us (See *Revue des Cours Scientifiques*, March 13th, 1869, p. 232).

As to the comments made on our conclusion regarding carbonic oxide, that "of all known gases" it gives the highest calorific effects, I am quite ready to confess that Mr. Watts has convicted us of a lack of precision of language which we ought to have avoided. We may, however, plead in mitigation, that our paper was more especially intended to introduce the subject to *practical men*, in available forms; and that we, therefore, with an inadvertence not wholly excusable, held in mind only such gases as are met with appreciably in practice. Mr. Watts therefore puts us again under obligation here.

Some readers will doubtless conclude, from Mr. Watts's last paragraph, that he suspects Professor Silliman and myself of ignorance regarding the experiments of Bunsen and Deville on the actual temperatures of the flames of hydrogen and carbonic oxide. The readers of this journal will not heed such an insinuation, in view of discussions by the present writer, of the researches of these two chemists, that have appeared in these columns, antedating the presentation of the joint Salem paper. (See particularly *American Gas-Light Journal* of August 2nd, 1869, p. 34.) One sentence in that paper might, I should think, have presented such an impression on the part of Mr. Watts. This is where we say that our figure 6851° C. "is the temperature actually possible in the flame of the compound blow-pipe *were the combustion instantaneous and complete*" (the italics being in the original). The subject belonging, however, to that of flame-temperatures, which we had not as yet strictly entered upon, was deferred by us for the time being.

Finally, I cannot but submit that Mr. Watts in presenting his concluding table, has in several ways inadvertently laid himself open to criticism of a class similar to most of that applied to us, including the accusation of confusion of ideas and terms. I shall be satisfied with respectfully presenting two questions. If the second column comprises the actual flame-temperatures, as determined by experiment, why does he designate the first column also "flame-temperatures"? Are not these latter figures precisely what we have designated as *total calorific powers or effects*, instead of temperatures?

ON THE EFFECTS OF THE APPLICATION OF THE HOT BLAST TO BLOWPIPE PURPOSES:

AND THE PROPOSED SUBSTITUTION OF HEATED AIR FOR
OXYGEN IN THE PRODUCTION OF CERTAIN THERMAL
AND ILLUMINATING EFFECTS.

By W. SKEY,
Analyst to the Geological Survey of New Zealand.

THE useful and well-known effects of the hot blast, in the process of iron smelting, has induced me to try and extend it profitably to other purposes, beyond that which prompted its application in the present instance.

My experiments, as yet, have been confined to testing the effects of substituting a hot blast for a cold one, as hitherto used, for the production of the well-known blowpipe flame; a flame so produced will be expected to have its thermal and illuminating effects augmented, but scarcely,

perhaps, to that degree which experiment has demonstrated.

I had better state, at the outset, those particulars which it is necessary to know, before relating the results.

The temperature of the blast was, approximately, 500° F.; the diameter of the jet, regulating its issue, was 1-30th of an inch; the combustible for receiving the blast was stearine.

This flame manifested a very marked superiority over the common blowpipe flame—substances difficult to fuse in the latter, magnetite, potash-felspar, mica, readily yielded under these circumstances; while thick glass tubes, half an inch in diameter, and hard German glass tubes, were tractable to an eminent degree.

Carrying my test experiments still further, I found several substances, for the fusion of which the oxyhydrogen flame, or some equivalent of it in heating power, is said to be indispensable, also yielded before the blowpipe-flame thus urged: for instance, platinum, pipe-clay, fire-clay, agate, opal, flint.

Several samples of each were tried, and always with the same results; it could not well be, therefore, that the fusibility of any of these substances was due to the accidental presence of foreign matter, in more than usual quantity.

The platinum was the common platinum foil, also a sample prepared especially for the purpose; the only impurity found in it was iron, as traces, communicated to it in the act of forging; possibly minute quantities of some of the other metals of the platinum series might be present, but they would rather tend to increase its infusibility than otherwise.

Alumina only appeared to vitrify; while, after numerous trials with crystallised quartz, I could not succeed in fusing it to a globule; thin splinters, however, curled round upon themselves, like scolezite, and ultimately assumed a glazed appearance, clearly showing that the melting-point was all but reached.

It appears, from this, that a very small amount of some foreign substances exercises a marked effect upon the fusibility of silica, agate, opal, &c., being only a little less pure than rock crystal, though so readily fusible in this flame.

Regarding the illuminating power of the flame so produced, when allowed to impinge upon a solid substance, such as lime or magnesia, it was not only more intense (as would be expected), but the volume of incandescent matter was largely increased.

Before I proceed to urge the further use of hot air for combustions, where high temperatures are necessary, I wish to call attention to the fact, that the temperature of the flame, which I have hitherto worked with, can be largely and economically increased by increasing that of the blast; this can easily be done to a threefold extent.

By substituting heated hydrogen (or burnt coal-gas), I have also realised all the effects just instanced, with greater rapidity and decision; but the great diffusiveness of this gas, especially when heated, has prevented me, as yet, carrying the experiments further.

While on the subject of heating both combustibles (at least, both the substances which take part in these combustions), I cannot refrain from remarking how easily the temperature of the oxyhydrogen flame, even, could be increased in this manner—the gases would, of course, have to be heated prior to contact. Upon their more vigorous diffusiveness, when rarefied, I should rely for that solidity of flame so necessary where the communication of very high temperature is desired. The jets regulating the issue of the gases would have to be very fine.

Proceeding now to the next part of this subject: the result of these experiments, instanced, urge me to recommend, for trial, the substitution of heated air for oxygen, in most of those cases where this gas is now employed in conjunction with hydrogen, or other combustible matter, as a generator of heat or light: for instance—

1. In the metallurgy of platinum, that part of it where the metal has to be fused; also in soldering platinum stills for sulphuric acid works.

2. The fusion of alumina in the manufacture of certain gems.

3. In the production of the Drummond and Bude lights.

The fusion of platinum and alumina is now effected by the oxyhydrogen flame.

Relative to the competency of heated air to perform the part of cold oxygen in the production of such intense lights as these (the Drummond and the Bude), I think this can be demonstrated, almost to a certainty, in the following way:—

Thus—the flame employed in these investigations has certainly a minimum temperature of 4596° F., since this is the fusing point of platinum, the substance most easily fused of all those I have tried that are infusible in the common flame; doubtless the temperature is considerably higher, but I will take these figures. On the other hand, the actual temperature of the lime, when the Drummond light is in operation, is (on the authority of Tyndall) only 2000° C. = 3632° F.; hence this flame has an excess of temperature over that of the incandescent lime equal to 964° F., a pretty good margin for loss, surely sufficient if properly economised; but as I have already shown, this excess of temperature can be largely increased.

In view of the greater controllability of the proposed substitute, the absence of all danger in its use, its not requiring chemical preparation, and its cheapness, compared with oxygen; upon these several points, respectively, the question should be properly tested.

Besides the substitution of oxygen urged above, the possible fusion of the purer clays, and certain silicas, &c., in a ready and economical manner, may induce the further utilisation of these substances, while, in experimental chemistry, the facility with which such high temperatures can be attained and kept up may lead, among other things, to some cheaper way of extracting certain metals from their oxides—aluminium, for instance, from alumina or clay.

On reviewing these results, it does seem not a little singular that a difference of not more than 500° F. in the temperature of the blast should make the difference between the fusibility and infusibility, of such substances as platina, agate, fire-clay, &c., in the blowpipe flame. It will be recollected, however, that the blast has, in this case, not only taken up the heat required to raise a single volume of it to this temperature, but another portion of heat has been taken up in a latent form, as the air expanded,—consumed as it were in lifting against the atmospheric pressure; this may be represented sufficiently well for us, by assuming the temperature of the blast, kept to its normal volume, at 700° F.

This is as yet, however, but a very slight addition to produce results, which so nearly approximate to those obtainable by the oxyhydrogen flame, seeing the latter has an estimated temperature of $14,000$ to $15,000^{\circ}$ F., while that of the present method does not much exceed 5000° F. The gap, as far as effects is concerned, is narrowed so much, and in a manner so unexpected, by the results here given, that one is naturally prompted to enquire whether the assigned temperature of the oxyhydrogen flame has been obtained by direct experiment, or by calculations, based upon the ascertained temperature of other flames. The temperature as calculated, indirectly, in this last way, certainly furnishes us with figures remarkably close to those just quoted.

In reference to this important point I beg to call attention to a notice, which appeared in the *CHEMICAL NEWS*, relative to the imperfect combustion of certain gases at high temperatures.

There we learn that at moderately high temperatures

(much below $10,000^{\circ}$ F.) oxygen and hydrogen only very partially combine,—from memory, I believe, not more than to the extent of half their weight,—the remainder of the gases of course combine, as the centre of heat is left behind. Thus, although the quantity of heat evolved by their combustion is the same, being divided over a larger volume, its intensity is proportionately diminished.

This being so, it would seem to follow that the temperature of the oxyhydrogen flame must be very considerably lower than that hitherto ascribed to it; and, therefore, the possibility of substituting it in this, or in some other manner equally economical, for the several purposes here specified, appears so much the greater.

OBITUARY.

DR. P. BOLLEY.

WE regret to learn that Dr. Bolley, the celebrated chemist and technologist, died suddenly on the 3rd inst. The deceased was born at Heidelberg, in 1812; received his preliminary and university education in his native town; and, in 1836, took the degree of Ph.D. For some time after that period, he was the first assistant of the late Professor Gmelin; in 1838, he was appointed Professor of Chemistry of the Cantonal School of Aargau (Switzerland); while, in 1843, he was elected Director of the Polytechnic School of that town. These positions he exchanged, in 1854, for his appointment of Professor of Chemistry and Technology at the Federal Polytechnic School, at Zurich, after having first become, in 1850, a naturalised Swiss citizen. From 1859 to 1866, Dr. Bolley was Director of this school, which difficult post he filled to the full satisfaction of the Swiss Federal Government, and, by his exertions, this institution became one of the most prosperous and most frequented of the Continent, the number of pupils having increased from 109 to 550, among whom were 314 foreigners from almost all parts of the world, including such remote countries as Chili, Peru, &c. In the years 1851 and 1862, the deceased was sent to London by the Swiss Federal Government to report upon the exhibitions; and, in 1867, he visited Paris for the same purpose. Dr. Bolley's published works are very numerous. He first started, and was for some time chief editor of, the *Schweizerische Gewerbeblatt* (from 1840, and continued to the present day); he was also one of the chief contributors to the *Schweizerische Polytechnische Zeitschrift*; and, in company with several eminent savants, he edited a most complete and valuable work on Chemical Technology, in the German language, of which work he had, just before his death, finished the section on Natural and Artificial Dyes and Pigments. Dr. Bolley also published a Manual of Technico-Chemical Research, which was originally issued in the German language, but has been translated into English and French. The deceased was highly respected in every way, and his sudden demise is a very great loss to the Helvetian Republic, of which he was an eminently useful and valued citizen. As might be expected, the deceased was a member of very many scientific societies in various countries. The Swiss Federal Polytechnic School above alluded to is an institution established at the expense of all the Swiss cantons, jointly, and under the chief management of a committee, elected from among the national council for a period of five consecutive years; the Director of the school is the chief executive of the establishment, under the aforesaid committee, among which generally scientific men of note are found as members. This school is arranged upon the plan of that adopted for the school alluded to in the *CHEMICAL NEWS*, vol. xxii., p. 58.

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Notes of a Course of Seven Lectures on Electrical Phenomena and Theories. By Professor TYNDALL, LL.D., F.R.S.

(Continued from p. 68.)

Electric Polarisation: Ritter's Secondary Pile.

234. When an electric current is sent through acidulated water a film of oxygen covers the positive electrode, and a film of hydrogen covers the negative electrode. One of these two substances being electro-positive, and the other electro-negative, they act in the liquid like two different metals; the hydrogen plays the part of zinc, and the oxygen plays the part of platinum.

235. Interrupting the primary battery circuit, and uniting together the two plates covered with their respective films, an electric current is obtained.

236. The direction of this current is from the hydrogen film to the oxygen film in the liquid, and from the oxygen film to the hydrogen film through the connecting wire.

237. Two electrodes thus covered with condensed gaseous films are said to be *polarised*: and the currents obtained from them are called currents of polarisation.

238. Now the battery current being always from oxygen to hydrogen (see Note 211), it is plain that the current of polarisation is always opposite in direction to the battery current employed to polarise the electrodes.

239. When a decomposition cell with platinum plates is introduced into a voltaic circuit, it is found that the battery current, though strong at starting, gradually sinks. This sinking is due to the gradual development of the antagonistic current of polarisation.

240. Also in the cells of the battery itself this current of polarisation may come prejudicially into play. When two metals, say zinc and platinum, and one liquid, say acidulated water, are employed, the platinum plate is coated with a film of hydrogen.

241. This hydrogen, being electro-positive, resembles a plate of zinc, so that when it is present we have, as it were, zinc opposed to zinc in the battery.

242. Were both plates actually of zinc we could have no current; and with the hydrogen film which approximates to zinc we have only a feeble current. To get the full effect of the zinc and platinum some means must be devised to remove from the platinum its film of hydrogen.

243. This is effected in Grove's battery by the employment of two liquids. The one is strong nitric acid, which contains the plate of platinum; the other is dilute sulphuric acid, which contains the plate of zinc. The nitric acid is placed in a vessel of porous earthenware, which becomes saturated with the liquid and allows the current to pass through it.

244. When the current passes, the hydrogen liberated at the platinum electrode in Grove's cell is instantly oxidised by the nitric acid, and prevented from forming a film upon the surface of the platinum.

245. If instead of employing a single decomposition cell and a single pair of platinum electrodes, we employ a series of such cells, and send the same current through them all, we convert every pair of such plates into an active voltaic couple; and if the number of such couples be great, effects of great intensity may be obtained.

246. If instead of using decomposition cells we simply employ a series of plates of the same metal, say a series of half-crowns, separated from each other by pieces of bibulous paper or by bits of cloth wetted with acidulated water; on sending a voltaic current through such a pile of plates, we liberate on one of the surfaces of each plate a film of oxygen, and on the other surface a film of hydrogen. These play the part of the two different metals in the pile of Volta.

247. The electro-motive force of such a pile may be far greater than that of the battery which charges it. It may produce a far more brilliant spark, and urge its current against resistances which would be quite insuperable to the original battery current.

248. The discoverer of this form of pile was Ritter; it is sometimes called the *secondary pile*, to distinguish it from the battery which charges it.

Faraday's Electrolytic Law.

249. When the self-same current is sent through a series of cells containing various compound liquids, the same amount of liquid is not decomposed in all cases.

250. Let the current be sent in succession through a series of cells containing water, oxide of lead, chloride of lead, iodide of lead, and chloride of silver; then taking them in the above order, the weights of the liquids decomposed are represented by the numbers 9, 111.5, 139, 230.5, 143.5.

251. The question now is, how are these weights of the respective substances divided between the two electrodes? Supposing the numbers to express grains, we should have the following division between the electrodes:—

At the positive electrode. Grains.	At the negative electrode. Grains.
Water 8.0 oxygen	1.0 hydrogen.
Oxide of lead . . . 8.0	103.5 lead.
Chloride of lead . . 35.5 chlorine	103.5 "
Iodide of lead . . . 127.0 iodine	103.5 "
Chloride of silver . 35.5 chlorine	108.0 silver.

252. Now these numbers express the combining proportions of the respective substances; by the electric current in all cases the law of combination as regards quantity is exactly inverted. The substances combine in equivalent proportions; they are decomposed in precisely the same proportions. This is the celebrated law of electrolysis discovered by Faraday.

253. In no case in the body of the electrolyte is any decomposition observed; in no case is any gas there liberated. The substances set free appear at the electrodes, and there alone.

254. Taking water as an illustration, the process is to be figured thus:—When the electrodes, charged with electricity from the battery, are plunged into the liquid, the oxygen atom of the water turns towards the positive, and the hydrogen atom towards the negative electrode.

255. If the electro-motive force be strong enough, the oxygen is torn away from its hydrogen; the free hydrogen immediately converges its attraction on the next adjacent oxygen atom, and unites with it, dislodging at the same time the hydrogen with which that atom had been previously combined. Another atom of hydrogen is thus liberated, which in its turn decomposes the adjacent water molecule. Thus through the chain of molecules run a series of decompositions, followed by immediate recompositions, until the negative electrode is reached. Here the hydrogen, having no further oxygen with which to combine, is liberated as a gas. This is the theory of Grothuss, which, at all events, fairly embraces the facts.

Nobili's Iris Rings.

256. The hardness of steel in tempering it is judged by its colour, which is due to a film of oxide overspreading the steel. The oxide which forms on the surface of molten lead also shows vivid colours.

257. These are the colours of *thin plates* investigated by Newton and explained by Thomas Young.

258. By electro-chemical decomposition Nobili produced such colours in a very beautiful manner. Placing, for example, a polished steel plate in a dilute solution of acetate of lead, and connecting the plate with the positive pole of a voltaic battery, on dipping the end of a wire connected with the negative pole into the solution, the peroxide of lead is liberated on the surface of the steel immediately under the wire; and a film gradually diminishing in thickness spreads from that point outwards.

Round this point we have a series of concentric circles showing vivid iris colours.

259. These colours, like all those of thin plates, depend upon the thickness of the film, which diminishes as the distance traversed by the current increases.

(Du Bois-Reymond has shown that when the point from the negative end of the battery is very near the steel plate, the thickness of the film corresponding to the different circles is inversely proportional to the cubes of their radii.)

Distribution of Heat in the Circuit.

260. When the two ends of a voltaic battery are connected by a thick wire of good conducting material the wire is not sensibly heated; the heat due to the oxidation of the zinc is in this case confined to the battery itself.

261. But if the two ends of the battery be connected by a wire that offers a resistance to the current, the wire is heated, and may, if properly chosen, be raised to a white heat.

262. Considering the battery as the hearth where the zinc is burnt, we might be led to infer that the heat due to the combustion of the zinc is liberated on the hearth itself, and that its amount depends solely upon the quantity of zinc consumed.

263. This, however, is not the case. Let the battery, with its two ends united by a thick wire, be surrounded by a vessel of water, to which the heat developed by the oxidation, say of an ounce of zinc, is communicated; the quantity of heat developed is measured by the rise of temperature of the water.

264. Let the battery, with its two ends united by the resisting wire, be placed in the same vessel, and let the heat generated in the battery by the oxidation of an ounce of zinc be again determined; this heat will be less than that observed in the last experiment.

265. If the connecting wire be now enclosed in a separate vessel, and if the heat generated in the wire be thus determined, on adding this amount of heat to that liberated in the battery, a total heat is obtained exactly equal to that generated in the battery alone, when the good conducting wire was employed.

266. In fact, the absolute amount of heat generated by the oxidation of an ounce of zinc is perfectly constant; but it may be distributed in various proportions between the battery and the external circuit.

Relation of Heat to Current and to Resistance.

267. On what does the heat developed in a wire uniting the two ends of a voltaic battery depend?

268. It depends, in the first place, on the strength of the current, but it is not simply proportional to that strength.

269. Let the strengths of a series of currents, determined either by the tangent-compass or the voltmeter, be represented by the numbers 1, 2, 3, 4, then the quantities of heat developed in the same wire by these respective currents are expressed by the numbers 1, 4, 9, and 16.

270. The heat generated is therefore proportional to the square of the strength of the current.

271. Preserving the strength of the current constant, the heat generated is proportional to the electrical resistance of the wire through which it passes. These important principles were established by Joule.

272. Thus if one of two equal currents pass through a silver wire, and the other through a platinum wire of the same length and thickness, the heat generated in the platinum will be ten times that generated in the silver, because the resistance of the former is ten times that of the latter. To urge the current through the platinum in this case would, however, require greater battery power than that necessary for the silver.

273. Hence, when the same current is sent through a wire composed of alternate lengths of silver and platinum

of equal thickness, the platinum spaces may be raised to a white heat, while the silver is not raised to the faintest glow.

(To be continued.)

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, August 16, 1870.

As may be expected, from various causes to which it is unnecessary to allude, this number is a very small one, the meeting of the Academy having only lasted about twenty minutes. The original papers and memoirs relating to physico-chemical and allied sciences are the following:—

Decimal Division of Angles and Time.—Y. Villarceau.—This lengthy paper contains a very concise review of the reasons in favour of the application (for scientific purposes, at least) of the decimal division of the objects alluded to.

Reply to the Note of M. Jamin published in the preceding number of this Periodical.—H. Sainte-Claire Deville.

The Sun.—Rev. Father A. Secchi, S.J.—The author, while passing through Paris, presents to the meeting his work on the above-named subject just published in the French language. This volume is divided into three parts; the first is devoted to the explanation of the modern means and methods of observation, and describes the structure of the sun; the second portion treats of the influence of the sun in the universe; while the third part describes the relations of the sun to the stars. The author states that he feels confident that this work contains everything relating to this subject which has been discovered and investigated by the various savants of the whole world who have devoted their labours to this matter.

Normal Amylic Alcohol.—A. Lieben and A. Rossi.—In order to prepare this new alcohol, the authors have first procured normal cyanide of butyl and the valeric acid corresponding thereto, which is isomeric with that produced by the oxidation of ordinary amylic alcohol. This new acid boils at 185°, and yields regularly-crystallised salts. The lime-salt of this new acid, having been mixed with formate of lime, and submitted to dry distillation, produced an aldehyde which, on being hydrogenised, produced the new alcohol; this, in many of its properties, resembles the fermentation amylic alcohol, but differs therefrom by a higher boiling-point (137°). The authors have prepared, by well-known methods, the chloride, bromide, iodide, and acetate of amyl, all of which ethers differ from the ordinary amylic ethers by a higher boiling-point. The formula of this new amylic alcohol is—

Experimental Researches on the Modifications of the Immediate Composition of Bones.—F. Papillon.—The author relates, at length, some experiments instituted with live animals, to which were given, among their food, phosphate of strontia, phosphate of alumina, and phosphate of magnesia. These experiments were continued for several months, and the animals (pigeons and rats) which did not seem to be in the least affected by partaking of the small daily doses of the mineral matters alluded to, were killed, and their bones submitted to analysis, with the following results:—Ash of bones of pigeon, in 100 parts—Lime, 46.75; strontian, 8.45; phosphoric acid, 41.80; phosphate of magnesia, 1.80; residue, 1.10—total, 99.80. Bones of a rat, in 100 parts—Alumina, 6.95; lime, 41.10. Bones of another rat (to which phosphate of magnesia had been given), in 100 parts—Magnesia, 3.56; lime, 46.15.

Bulletin Mensuel de la Société Chimique de Paris, July, 1870.

From the *procès verbaux* of the meetings of this Society held in May last, and published in this number, we quote the following:—

Researches on the Vapour Density of Perchloride of Phosphorus.—Dr. Wurtz.—It is a known fact, says the author, that, when this compound is brought to the state of vapour, it is dissociated into protochloride of phosphorus and chlorine, in such a manner that its vapour occupies 4 volumes instead of 2. The author, thinking that this dissociation might be greatly retarded by the presence of a large ex-

cess of one or other of the products of this dissociation, has taken the vapour density of perchloride of phosphorus, by causing its vapour to be diffused through the vapour of protochloride, and, by this means, has obtained results coinciding with those which theory indicates for 2 volumes of vapour. The experiments were made according to M. Dumas's method, by introducing, into a previously-weighed glass balloon, perfectly dry perchloride of phosphorus, with an excess of protochloride, and heating to from 166° to 190° in a paraffin bath. The theoretical vapour density (2 volumes) is 7.2; the results of the experiments alluded to vary from 6.25 to 7.42.

Action of Iodide of Cyanogen upon Oil of Turpentine.—MM. de Clermont and Schützenberger.—When these substances act upon each other at 60°, there is formed an iodine-containing liquid and a syrupy nitrogenous substance. The former body yields, when treated with an alcoholic solution of caustic potassa, or with moist oxide of silver, a solid camphor-like substance. When a cold ethereal solution of iodide of cyanogen acts upon the oil of turpentine, a tarry substance is obtained, and an iodine-containing liquid, which, if distilled in vacuum, explodes at about 100°. When iodine acts upon oil of turpentine, it appears that identical bodies are produced. The authors continue these researches.

This number contains, further, the following original papers:—

Observations on the Critical Remarks made by M. Thomsen in reference to the Calorimetric Methods of MM. Favre and Silbermann.—H. Sainte-Claire Deville.—This paper is written chiefly to prove that the mercurial calorimeter is a suitable and proper instrument for accurate experiments, if used according to the rules and indications given by M. Favre.

Solid Cresol.—A. Wurtz.—This paper contains the description of a process for obtaining the body alluded to, by treating hydrocarbons with sulphuric acid, and decomposing the conjugated sulpho-acids by potassa. The author states that he (as has been also observed by M. Barth, who has been experimenting on this subject) found that, during the reaction, some salicylic and paroxybenzoic acids are formed.

Some Compounds Homologous with Tartaric and Malic Acids.—H. Gal and J. Gay-Lussac.—This paper contains the following chapters:—Adipo-tartric, adipo-malic, subero-malic, and subero-tartric acids.

Action of Chlorhydric Acid upon Osseine; New Researches for the Estimation of Osseine in Fossil-Bones.—A. Scheurer-Kestner.—This paper is mainly a reproduction of the author's paper on this subject as published in the *Comptes Rendus*, and already abstracted therefrom by us.

Manufacture of Tam-Tams, or Gongs, and Cymbals.—A. Riche and P. Champion.—This paper contains an account of the method now followed for making the sound-producing instruments alluded to, which consist of an alloy of 80 parts of copper and 20 of tin, which is hammered out with frequent annealing. An alloy of 78 of copper and 22 of tin answers better, and can be rolled out. The process is similar to that in use in China, and is carried out at Paris by M. Caillat.

New Series of Platinum Compounds.—Dr. P. Schützenberger.—This paper contains, at great length, all the particulars relating to a new series of platinum compounds discovered by the author, and already referred to by us from his paper in the *Comptes Rendus* on this subject.

Abstract of a Memoir on the Volumes of the Chemical Equivalents.—(First part.)—M. West.—This memoir consists of five parts, and treats of a statistic of more than 600 volumes of equivalents, the volumes being taken from all the densities mentioned in published classical works. This memoir is certainly of great value, but, unfortunately, not suited for any useful abstraction, and by far too lengthy for reproduction in full.

Polytechnisches Journal von Dingler, first number for July, 1870.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Artificial Production of Cold by Compression and Expansion of Air.—H. Bruhn.—This paper contains a review of the conditions required for the construction of machines contrived for the purpose of producing cold by the alternate compression and sudden expansion of air. The author proves that, although it might be possible to produce a very great cold by the means proposed, it fails to be economical in any respect.

Injurious and Poisonous Action of the so-called Tar Colours.—Drs. H. Eulenberger and H. Vohl.—The authors of this very lengthy memoir have, in writing it, kept in view the following points:—Is the pigment or dye prepared from substances which are by themselves poisonous? Has there been left in the pigment or dye any substance used during its preparation which, although not strictly belonging to the constitution of the pigment itself, is poisonous? Does the chemically-pure dye or pigment act injuriously on the animal body? Does the application and fixing of the dye to textile fabrics require mordants which are by themselves injurious, and a portion of which, either large or small, may remain in the fabric? The memoir is further divided into the following sections:—Aniline dyes; arsenical aniline green and picric acid; phenyl dyes.

Experiments on the Activity of the Süvern Disinfectant.—M. Hausmann.—The disinfectant alluded to consists of lime, chloride of magnesium, coal-tar, and water, in variable proportions. The mixture applied for experimenting contained, upon 240 parts of water, 100 of lime; 10, 40, or 70 of chloride of magnesium; and 6, 12, or 18 of

coal-tar. This mixture has been tried for the disinfection of foul canal water, with the result that 1000 parts, by weight, of the latter required 10 parts, by weight, of the disinfectant for complete purification. Some experiments were instituted with each of the essential constituents separately, to try their efficacy in this respect; lime alone seems to be most active. Nothing is said about the nature or cause of the foul state of the canal water alluded to.

Purification of Oil of Turpentine.—Dr. Grüner.—The author says that, even the most carefully rectified oil of turpentine leaves, when applied for cleaning tissues or leather, an unpleasant smell after its evaporation. He states that this is entirely obviated if the oil is rectified by distillation over tannin, but no rationale of the action of tannin is given. The tissues treated with this oil should be dried at a temperature of 65°, and no smell will adhere to them.

Annales du Génie Civil, July, 1870.

This number contains, in addition to a series of papers on engineering, the following paper relating to chemistry:—

Madder: its Application to Dyeing and Printing.—D. Kæppelin.—The first portion of a lengthy memoir, giving, in the first place an account of the history of the dispersion of madder from its native soil into Europe, where it was re-introduced from the Levant by the Dutch, in the 16th century. By order of Charles V. it was cultivated in the Alsace, and, since 1789, in the then Comtat d'Avignon (now Département de Vaucluse). The author describes, at great length, the mode of cultivation of *Marena madder*, grown in the Derbent (a portion of Russia, formerly a Persian province). The soil of that district is a rich alluvial clay, containing a large quantity of calcareous matters and humus; the madder seed is sown in the November, and the roots are collected in the fourth following spring (April). The roots are first placed in well-aired sheds, and next submitted to a peculiar process of steaming, by being placed in what may be termed tanks dug in the soil, 2 metres deep and 1 wide. These tanks are first heated, by means of the combustion of wood, to such an extent, that the sides become red-hot; when this is effected, the madder-roots, previously watered, are thrown upon the smouldering embers; and when the hole is filled, covered over with coarse woollen cloths, and left in the hot tanks for six hours; the roots are then removed, and next dried in the sun. A great portion of this paper is, by the acknowledgment of its author, who has been in Russia, abstracted from the works of MM. Persoz, Girardin, Schützenberger, and others.

Journal für Gasbeleuchtung (two numbers), May and June, 1870.

These numbers contain the following papers relating to chemical-physical subjects and collateral sciences:—

Philipp's Carboxygen Illumination.—O. Kellner.—The author describes, at great length, the process of the manufacture of oxygen from protochloride of copper, obtained by heating the chloride of that metal, which, in order to prevent its caking together, is mixed with 33 per cent of broken pottery-ware. When submitted to heat, chlorine is first given off, according to the formula—

When the protochloride is exposed to moistened cold air, an equivalent of oxygen is taken up for that of chlorine previously given off, yielding—

This taking up of oxygen goes on very rapidly, even with large masses, but becomes almost instantaneous in the presence of steam and air at 200°; while, at 400°, the oxygen taken up is given off again, and only requires cooling for the purpose of condensing the watery vapour it carries; after condensation, it is at once collected in gasholders. The cost price of the protochloride of copper is, in Germany, about 1s. 6d. per kilo.; 50 kilos. of this material yield from 1.3 to 1.5 cubic metres of oxygen gas.

Photometrical Studies.—Dr. F. Rüchhoff.—Third and concluding portion of this lengthy paper.

Communications from the Committee of the Society of German Gas Engineers in reference to the Supply of Water to Towns.—This very interesting and lengthy memoir is divided into the following sections:—Waterworks of Hamburg; introduction and history; sources of supply; pumping machinery; canalisation and distribution of mains; regulations for the supply and use of the water; waterworks of Altona; waterworks of Vienna; waterworks of Schweidnitz (Silesia, Prussia).

Report of the General Annual Meeting of the German Gas Engineers at Hamburg, May 23–26 last.—This lengthy memoir contains nothing but what directly relates to the peculiar subjects discussed at such meetings. Chemical subjects have not been treated.

Revue Universelle des Mines, de la Métallurgie, et des Travaux Publics de Belgique, No. 2, 1870.

This number contains the following original papers and memoirs:—

Agglomeration of Fuel.—A. Habets.—The second portion of this very lengthy essay, illustrated by engravings, and chiefly treating of the best means of usefully applying the large quantity of small coal which becomes wasted at and near collieries and coal-pits.

Manufacture of Cast-Steel by means of the Refining of Pig-Iron with what is termed Intermolecular Combustion.—S. Jordan.—This lengthy memoir contains the following chapters:—General review; combustion of iron, of manganese, of carbon, of silicon; refining by means of atmospheric air; refining by means of steam; refining by means of oxygen.

Researches on the Permanent Motion of Gases through Pipes and Tubes.—Dr. Grashof.—An algebraico-physical essay.

Annales des Mines, No. 3, 1870.

This number contains the following original papers and memoirs relating to physico-chemical and allied sciences:—

Geological Notes on Oceania, the Islands of Tahiti and Rapa.—J. Garnier.—A very lengthy and valuable monograph on the geology of these far-distant countries.

Process of Desilvering Lead, as Executed at the Works of MM. Herbst, Brothers, at Call (Eifel, Prussia).—R. Zeiller and A. Henry.—The authors describe, at length, a peculiar process of desilvering lead by the aid of zinc, especially suited for the conditions of the works where these manipulations are carried out. The authors state that the process is effective and cheap in every respect, labour included.

Accident in a Beet-Root Sugar-Works at Cruzin (Nord, France).—J. Callon.—It appears that one of the steam-boilers of the beet-root sugar-works of MM. Miroux and Co., at Cruzin, after having been out of use for several months, had to be cleaned before being put in operation again. The water contained in the boiler at the time of stopping its work had been left off by the usual means; but, from some cause or other, the boiler and brickwork of the furnace (as found after the accident to be mentioned) had become slowly inclined backward, and, as a consequence thereof, a portion of the water was left; nothing, however, indicated, on opening of the man-hole, that the air in the boiler was greatly vitiated and unfit to support life. One of the workmen, who entered the empty boiler for the purpose of cleaning it, was, on approaching the end of it where the water had remained stagnant, almost instantly killed by the putrid miasms given off; and the man who dragged the almost lifeless body out of its dangerous position was saved with difficulty. The author of this paper, who is a member of the Central Committee for the Surveillance of Steam-Engines, states that no other case of such an accident having occurred is on record, but that the cause is undoubtedly due to the vitiated air in the confined space, the vitiation being caused by the putrefaction of organic matters collected in the water left in the boiler.

Mineral Resources of the Arige.—(Third part.)—M. Mussy.—The concluding portion of this lengthy monograph. This portion includes the mineral waters, with analyses, but their number is too large for specific quotation here.

Bayerisches Industrie und Gewerbe Blatt, May, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Depositing Zinc upon Copper or Brass, in the Wet Way.—Dr. R. Böttger.—The author first prepares finely-divided zinc, by pouring the molten metal in a previously strongly heated iron mortar, and stirring until nearly cold. The pulverulent zinc thus obtained is placed in a porcelain vessel, and to it is added a concentrated aqueous solution of sal-ammoniac. This mixture is heated to boiling; and the copper or brass objects to be coated with zinc (but previously well-cleaned, and, best, even with an acid) are then placed in the liquid, wherein they become coated with a brilliantly-white adhering layer of zinc.

Chemical Investigation of a Bohemian Lager Beer.—A. Vogel.—The sample analysed had been kept for two-and-a-half years in casks; the liquor had a deep brown colour; its taste was pleasant, but not bitter. One litre of this beer contained—Water, 878.4 c.c.; extract, and other following substances, in grms., 70.5; alcohol, 48.6; carbonic acid, 2.3; sugar, 5.0; phosphoric acid, 0.58; nitrogen, 0.46; ash, 2.4.

Paper and Millboard from Peat.—M. Oppermann.—The author states that M. Halbach, paper maker at Leer (Hanover), has succeeded in employing, along with straw, the fibrous matters met with in peat bogs for the manufacture of coarse paper and millboard.

Bibliothèque Universelle et Revue Suisse.—Archives des Sciences Physiques et Naturelles, July 15, 1870.

This number contains the following original papers relating to physico-chemical and collateral sciences:—

Researches on the Magnetic Rotatory Polarisation of Liquids.—A. de la Rive.—This very lengthy memoir is divided into the following paragraphs:—Description of apparatus and method of experimenting; determination of the specific magneto-rotatory power of some liquids—viz., alcohol, sulphide of carbon, sulphuric acid, sulphurous acid; influence of the temperature upon the magneto-rotatory polarisation of liquids—viz., alcohol, iodide of ethyl, amylic alcohol, distilled water, and sulphuric acid, (HOSO₃); determination of the magneto-rotatory power of a mixture of two liquids; determination of the magneto-rotatory powers of some isomeric liquids—viz., acetate of amyl, valerate of ethyl, butyrate of isopropyl, amylic alcohol, hydrate of amylen; conclusions drawn from the experiments.

Cretaceous Formations met with in the Exterior Alps on Each Side of Lake Léman.—V. Gilléron.

Radical of Phthalic Acid.—E. Ador.—The author describes, at great length, the complicated reactions by which he obtained phthalyl, a crystalline compound, insoluble in water. Alcohol, ether, chloroform, acetone, sulphide of carbon, acetic acid, and carburets of hydrogen dissolve only a very small quantity of phthalyl; its best solvent is boiling phenic acid. Phthalyl is sublimable at a high temperature, and is strongly acted upon by bromine and sulphuric acid. The formula of phthalyl is C₈H₆O₄. Concentrated nitric acid converts phthalyl, at boiling heat, into diphtalic acid, C₁₆H₁₀O₈, a white, coloured crystalline substance, somewhat soluble in water, fusing at 259°, and yielding then anhydrous phthalic acid.

Les Mondes, August 11, 1870.

Pindray's Smoke-Consuming Furnace.—M. Tilloy.—The author, proprietor of a large factory, states that he has had constructed a 70-H.P. steam-boiler, with furnace and flue arrangement according to M. Pindray's plan, and that he has every reason to be highly satisfied with this arrangement, whereby he daily saves 15 hectolitres of coals; emits no smoke or combustible gases from the chimney; keeps up steam at full pressure, even when clearing the fires; whilst with the combustion at its greatest activity, the bottom of the fire-bars is hardly hot. We do not know what M. Pindray's arrangement really consists in, but we can readily affirm, by experience, that such results may be arrived at, even with multitubular marine boilers.

International Scientific Relations.—Dr. A. Boué.—The author calls attention to the fact, that a great many scientific publications of the northern and easterly parts of Europe remain, unfortunately, almost unknown, save in the countries where the languages (Swedish, Danish, Finnish, Lithuanian, Russian, Czech, Slavonic, Magyar, Polish, Neo-Greek, and Roumanian, to which may be added Dutch) in which they are published are vernacular. The author proposes that it would be an advantage if, for each of these publications, either a full translation or an abstract of the papers were simultaneously published in French, English, or German.

Use of Iron in Homer's Period.—F. De Hauer.—This paper, chiefly of historical interest, contains, among other interesting facts, the opinion, defended, that the oldest iron ever in use was of meteoric origin, and therefore contained nickel. That copper and bronze were far earlier known and used than iron or steel, which latter, however, have been well-known to all purely Germanic races probably before these metals were known in some more easterly countries.

Aspect of the Environs and Basin of Paris shortly before and during the First Apparition of Man.—E. Robert.—An archaeological-geological paper of value, but too lengthy and too special to admit of any useful abstraction.

Cosmos, August 13, 1870.

Composition of Rain-Water.—Dr. G. Tissandier.—The author has analysed some rain-water fallen at Paris on the 1st and 8th of July last. The portion (only some drops purposely collected on watch-glasses) which fell on the first-named date contained no less than 4.68 per cent of solid matter; microscopical observation proved the existence therein of debris of woven tissues, threads, coal-dust, starch granules, sand, and debris of wood. On being evaporated, a drop weighing 0.032 grm., and then seen under the microscope, was proved to contain crystals of nitrate of ammonia and crystals of common salt. On the last-named date, a litre of water was collected on the top of a roof in Paris; this water, on being analysed, yielded a total solid dry residue of 0.0658 grm., containing—Insoluble mineral matters, 0.008 grm.; insoluble organic matter, 0.0340 grm.; soluble salts, 0.0210. This rain-water was found to contain 0.020 grm. of nitrate of ammonia; and, since this salt contains 35 per cent of nitrogen, it follows that the 10 mm. of rainfall of the 8th of July carried down 70 grms. of nitrogen per hectare, besides the organic matter.

Ancient Glaciers of the Auvergne.—J. Marcou.—A lengthy geological paper. The author comes to the conclusion that glaciers have existed in the Auvergne before the volcano of the Puy de Dôme and Mont-Dore were uplifted.

TO CORRESPONDENTS.

* * * The STUDENT'S NUMBER of the CHEMICAL NEWS will be published on Friday, September 9th. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the Education, who have not yet forwarded the necessary information to our office for publication in that number, will confer a favour by sending it with the least possible delay.

A Reader, W. R., and others.—Professor Storer's work on Analysis is not yet out; it will be published in the United States. We do not know the price at present, but will give full particulars as soon as possible.

T. Dearden.—The preparation of precipitated colours is treated in Gentile's "Lehrbuch der Farbenfabrikation," and also in Cooley's "Cyclopædia of Practical Receipts."

Dr. Stenhouse, F.R.S., C. Tomlinson, F.R.S., and A. Liversidge, are thanked for their communications.

THE CHEMICAL NEWS.

VOL. XXII. No. 562.

EXAMPLES FOR PRACTICE IN QUANTITATIVE CHEMICAL ANALYSIS.*

By FRANK H. STORER,

Professor in Massachusetts Institute of Technology.

(Continued from p. 99).

EXPERIMENT III.—Estimation of Chlorine in Chloride of Sodium.

HEAT a quantity of pure powdered chloride of sodium in a porcelain crucible, in order to expel hygroscopic moisture. Weigh out about 4 grms. of the dry powder, place it in a glass flask of about a litre capacity, and dissolve in 200–250 c.c. of water. Heat the solution moderately, add to it a quantity of nitrate of silver solution, cork the flask and shake it strongly. As soon as the chloride of silver has become curdy and coherent, and the liquid clear, add to the latter a drop more nitrate of silver. If a fresh precipitate is produced, add as much more nitrate of silver as may seem fit, again heat and shake the liquor, and repeat these operations until the addition of a drop of nitrate of silver ceases to produce any precipitate. Wash from the cork any particles of chloride of silver which may adhere to it, fill the flask completely with water, close its mouth with a small glass plate, invert it in an evaporating dish (a No. V. Berlin dish will do) two-thirds full of water, and remove the glass plate, shake the flask gently until all the chloride of silver has fallen from it into the dish, then remove the flask from the dish by a sudden jerk, in such manner that none of the chloride of silver shall be thrown from the dish. Finally, transfer the precipitate from the dish to a 6-inch filter, and wash it with hot water, until the filtrate ceases to leave any residue when evaporated on glass. Dry the precipitate, transfer it to a porcelain crucible, taking care to leave as little of it as possible upon the paper. Burn the filter on the cover of the crucible, and afterward heat the precipitate in the crucible until the mass begins to fuse upon its edges.

Four grms. of chloride of sodium gave 9.7825 grms. of chloride of silver (=2.4192 grms. chlorine), or 60.48 per cent. Theory required 60.66 per cent.

(To be continued).

ON THE ACTION OF NUCLEI.

By CHARLES TOMLINSON, F.R.S.

THERE are a few points in the two notes by Mr. Liversidge that require notice.

1. *Do nuclei act when wet?*—This point was first noticed by Ziz, of Mayence, in 1809.† He found bits of iron wire, flint, glass, small coins, &c., caused supersaturated solutions of sulphate of soda to crystallise; but, if previously wetted, these bodies become inactive. In noticing these experiments a few years ago,‡ I attempted to define the conditions under which dry active nuclei may be rendered inactive while still dry; and I endeavoured to show that, “if previously wetted with water, they are not wetted by the solution when thrown into it, and, consequently, cannot act as nuclei, because the solution does not really come in contact with them.” It will be found,

however, that the statement, *nuclei do not act when wet*, is far too general in its terms. All that can be said is that they sometimes, or often, do not act, or they do not act at once, for it may happen that wet unclean nuclei do act after some hours; whereas, if such nuclei be boiled up with the solution, and so made clean, they never act, though the solution be kept for months and be shaken every day. Löwel also noticed* that rods of glass, &c., kept in cold water, become *partially*, or wholly, inactive. Such rods, partly immersed in sulphuric acid or caustic alkali, and dried out of contact with air, are wholly inactive to the extent of the immersion, as may be shown by plunging them into soda-water, boiling water, or a supersaturated solution of Glauber's salt. There will be no liberation of gas, or vapour, or salt, but, on inserting the unclean end, it will act as a powerful nucleus.

2. *What is meant by chemically clean?*—Having proved, I think, that bodies are *nuclear* or *non-nuclear*, according as they are not, or are, chemically clean, a definition of the term “chemically clean” was required. It was justly urged that a definition which excludes oils and fatty bodies could not be accepted, since these may be as clean as a catharised glass rod. After much experimental research, I arrived at the following:—“A substance is chemically clean whose surface is free from any substance foreign to its own composition.”

This definition is so far guarded, that it refers to *surface* only. A glass rod, for example, is regarded as chemically clean, even though a particle of carbon or oxide of iron be enclosed and shut off within it; but not so if that particle reach, and form part of, the surface itself. Such a particle, if porous, acts as a powerful nucleus in separating vapour from a boiling liquid, and it also may act as a centre of crystallisation in a solution. So, also, a phial may be chemically clean as to surface, even though it enclose nuclear particles; and “a mixture of wax, oil, soot, dust from the floor, sodic sulphate, soap, &c., melted together on a glass rod,” may be a clean surface of wax, enclosing unclean particles.

3. *Can the finger be made chemically clean?* In a paper on “Some Effects of a Chemically Clean Surface,”† I refer to the delicate test of chemical purity afforded by the motions of camphor on water. Camphor was rotating briskly in the surface of water, in four glasses, A, B, C, D, when I put my finger into A, my tongue into B, the glass C was emptied and filled up with water from a jug that was in domestic use, while D was emptied, wiped with a glass cloth in ordinary use, and filled up with clean water. Fresh fragments of camphor were scraped upon all four glasses, and they were motionless on A, C, and D, thus showing that the surface of the water in each of these cases had contracted a nuclear film. In the same paper it is shown that other phenomena which depend for their action on the state of chemical purity are at once arrested “if the finger or other chemically unclean body be made to touch the water.”

In a popular account of this paper given in one of the journals, I am made to say “that the finger cannot possibly be made chemically clean.” This statement was met by an experiment by Prof. Van der Mensbrugghe.‡ He admits that the motions of the camphor are instantly arrested if the water be touched with the finger, and adds, “Ces effets sont certainement dus à la couche grasseuse adhérente presque toujours aux doigts; car, si l'on a préalablement soin de se laver les mains avec de l'alcool, puis avec de l'eau distillée, le contact de la surface liquide avec le doigt n'arrête plus les mouvements du camphre.”

What I really did say, was, that the finger cannot be made chemically clean in the sense that a glass rod is so cleaned;|| since the finger, however protected from external influences, generates, of itself, a nuclear action. I

performed an experiment with the view to determine, if possible, how long the finger, being made chemically clean, would remain so. The finger was first thoroughly washed in a solution of soap, then in alcohol, and, lastly, under a stream of water, and so dipped into water, on the surface of which the camphor fragments were spinning briskly. The finger was retained under the surface of the water, and slid along about an inch in length of the surface of the glass below the water. In less than two minutes the camphor fragments were brought to rest, and they did not recover their activity.

I have, on several occasions, put the clean finger into highly supersaturated solutions of sodic acetate with no effect, until a smear was produced by drawing the finger with pressure against the side of the glass, when the solution immediately became solid.

In experiments of this kind the results may vary according as the skin is naturally moist or dry, soft or hard; just as it is said to happen occasionally when a chain of hands is formed for the passage of an electric shock, the skin of one pair of hands is so dry that it acts as an insulator for a weak charge. I think it likely also that, by passing the finger through flame, it might not arrest the camphor motions when first put into the water, any more than act as a nucleus when just dipped into a supersaturated solution of Glauber's salt.

4. *Is an iridescent film ever inactive?* I need not repeat what has been already said respecting the limitations to my definition of chemical cleanliness, namely, that oils and fatty bodies, if clean, are not nuclear in the lenticular state, but are so in the condition of films. Mr. Liveridge, if I understand him rightly, has noticed iridescent films of oil, &c., on the surface of a supersaturated solution of Glauber's salt, that did not act as nuclei. This does not agree with my experience, but I may remark that in researches on the action of nuclei some attention must be paid to temperature. Solutions vary so much in sensitiveness as the temperature rises or falls, that experiments that succeed very well in winter may fail altogether in summer. This is especially the case with weak solutions, which may be supersaturated in cold weather but are only saturated in warm; and, of course, when saturated only, the observations as to the action of nuclei fail to apply.

A striking example of this kind is afforded in a paper by M. E. Lefebvre* on the "Supersaturation of Calcic Chloride," in which a large number of bodies are tried as to their nuclear action, and arranged into classes according as they do or do not act; whereas if the solution of the strength indicated be sufficiently reduced in temperature any one of the bodies which are said to be inactive may become active. The films formed by oils on the surface of highly supersaturated solutions of sodic sulphate produce, in cold weather, very fine prismatic plates of the 10-atom salt with dihedral summits; whereas, the same film acting on a solution of the same strength in hot weather produces much smaller crystals, far less perfectly formed. A strong solution of calcic chloride may be quite passive to the action of nuclei in hot weather; but if the vessel be put into a freezing mixture it becomes highly sensitive.

Highgate, N., August 27th, 1870.

THE NIIN OF YUCATAN.†

A COMMUNICATION from Dr. Arthur Schott, late of the Scientific Commission of Yucatan, furnishes some descriptive statements concerning an insect, and the nature and uses of a grease-like or wax-like product, with the result of a chemical examination of its properties.

Among the numerous interesting natural productions of Yucatan, not the least remarkable is the niin (pronounced *neen*), the knowledge of which, and of its technical application, has survived the national independence of the gifted Maya race. The niin is the grease of an insect bearing the same generic name. The niin may be considered akin to the cochineal, also the product of a similar insect; but they differ essentially in their nature, one serving as a well-known dye, while the other finds its application as a drying oil.

The nature of the niin will be clearly understood by the annexed scientific analysis, made by Mr. V. G. Bloede, analytical chemist, of New York. The matter examined by that gentleman consisted of a small quantity which Dr. Schott brought some time before from the city of Merida, Yucatan.

The analysis is as follows:—

The Yucatan niin is a yellowish-brown, fatty mass, having a peculiar oily odour. In its general properties it seems closely allied to hog's lard or suet. It is neutral to test-paper, neither presenting acid nor alkaline reaction, though, when exposed to the air, it acquires a very faint tendency to manifest the former. Its melting point is about 120° F., though, when once melted, it still remains in a semi-fluid state with the temperature as low as 80° or 85° F. When cooled to 10° F., it becomes hard and brittle, like suet. At ordinary temperatures, that is, about 60° F., it is of a thick, pasty consistency, like ordinary lard. Its specific gravity at 60° F. is about 0.92.

Its Solvents.—In regard to solvents, the niin presents the same general properties as any ordinary animal fat. It is not soluble in either hot or cold alcohol, even after extended maceration. It is freely soluble in both hot and cold ether, with which it forms a yellow, oily liquid. It is very soluble in turpentine, with which it forms an oily liquid possessing peculiarly valuable properties for mixing delicate oil colours, of which I shall speak hereafter. It dissolves freely in benzine; chloroform, also, is among its best solvents.

Chemical Properties.—The niin, in its classification in organic chemistry, must undoubtedly be ranked among the drying oils, though its absorption of oxygen takes place rather more slowly than with many other oils. Nor is this slowness in drying accelerated to any extent by boiling it with oxide of lead. It is the first, or nearly the first, example we have of a thoroughly drying animal butter or solid fat. Like some others of the animal fats, it contains a distinct volatile acid peculiar to itself. As, for instance, butter contains butyric and caproic acid; goat's fat, hircic acid; so the niin contains an acid of a peculiar, pungent smell, which might be aptly termed niinic acid. Its chemical composition differs little from ordinary animal fats. Like others, it contains a fluid oil—oleine—and a solid containing stearic, margaric, and other fatty acids. A portion of the acids may be obtained by dissolving the niin in turpentine or ether. The oily portions pass into solution, while a solid precipitates, consisting of the acids indicated, which may be separated from the fluid by filtration.

Saponification.—A peculiarity of the niin seems to be its difficult saponification. The strongest ammonia procurable has no saponifying action on it. Even if the fat be digested in ammonia for several days, no liniment is formed, but a marked transition from yellow to red seems to be the only change produced. This change of colour depends merely on the action of ammonia on the colouring matter of the niin, which, like the yellow turmeric (*Curcuma longa*), changes to red as it assumes an alkaline reaction.

With potash, too, it saponifies but slowly and imperfectly, and a concentrated lye is necessary. With soda it forms a soap only after extended boiling with a strong lye. It is only after several hours' boiling with oxide of lead that it forms the so-called "lead soap," and then the product is very imperfect. From these facts we can at once deduce that the niin cannot be considered

* *Comptes Rendus*, March 28, 1870.

† From the Report of the United States Commissioners of Agriculture.

a "good saponifying fat," but belongs to the "drying oils."

Effects of High Heat.—When the niin is melted in a porcelain dish, and the resulting oil exposed to a continued and high heat (between 250° and 350° F.) for an hour, or until a considerable portion of it has evaporated, the residue in the dish will then be found to have assumed a tough, flexible, varnish-like condition—a gelatinous mass no longer soluble in turpentine, or affected by heat or cold, at least to a great extent.

If a piece of this gelatinised niin is placed on a piece of porcelain, moistened with turpentine, and ignited, another remarkable change takes place; for, if the plate is slightly inclined as the mass burns, a thick, yellow, resinous oil or gum flows from it, which possesses most remarkable adhesiveness, closely resembling a thick solution of india-rubber, but which does not dry, retaining its half-fluid consistency for several days. This is a most singular change, and one that is worthy of further investigation.

Change of Air.—When the turpentine solution of the niin is exposed to the air in thin strata for a few days, it acquires the properties of a resinous varnish; in fact, the change is so complete, that when some of the solution is poured on a piece of glass it dries almost equal to fine shellac varnish. This change is due to the absorption of oxygen. If further developed, this property will undoubtedly make the niin of the greatest commercial value. The film of varnish is very elastic, and, at the same time, hard, which renders it superior to some of the other gums. An alcoholic solution can also be formed, but this is more difficult.

Suggestions as to Use.—The extreme oiliness of the niin will undoubtedly make it very valuable for various purposes in the arts; and its "drying" solution in turpentine has no equal for mixing fine colours for artists. This turpentine solution of the niin produces a remarkable brightness in the colours prepared with it, and they dry rapidly. But the chief value of the niin, which will give it commercial importance, is its property of forming a resinous varnish when treated as before described, rendering it superior to shellac for some purposes. Another valuable application of the niin could be found in the manufacture of waterproof fabrics. A piece of the most porous Swedish filtering paper, saturated with a solution of the niin diluted in turpentine, will not allow a drop of water to pass through, even after standing in it for days. An excellent way of water-proofing would be to saturate the article with melted niin, and then expose it in an oven to considerable heat until the grease gelatinises. By these means the niin becomes insoluble, not only in water, but also in most of its solvents. If the niin can be obtained, as Dr. Schott says, in "unlimited" quantities, it will, doubtless, in time become of great commercial value.—*Scientific American.*

NOTE ON ITACOLUMNITE.

By Professor A. M. EDWARDS.

To those accustomed to the use of the microscope it is not a matter of surprise that persons who do not commonly employ that instrument in research should make very serious mistakes in interpreting what they think they see by means of it, the more especially when high powers of magnification are made use of. The delicacy of manipulation necessary to work with the microscope at all satisfactorily, and the education of the eye required for the proper seeing by means of it, are not generally understood, so that those who are not skilled microscopists are extremely liable to be led into error. What

I am inclined to consider a case of this kind has lately been brought to my attention, and I am persuaded to make a note of it, the more for the purpose of correcting a grave error in investigation, and one which is, strange to say, readily demonstrated to be an error.

In 1867 (*American Journal of Science*, vol. xlv.), Dr. C. Wetherill published a well-written and seemingly-exhaustive paper, setting forth some "Experiments on Itacolumnite, with the Explanation of its Flexibility, and its Relation to the Formation of the Diamond." In attempting to elucidate the flexibility of this rock he has made use of the microscope, and, in fact, mainly draws his conclusions from the revelations which he supposes that instrument makes. Some specimens of itacolumnite, varying in tint from almost pure white to a rusty red tint, and in texture from finely granular to coarse and distinctly laminated, having come into my hands, I have been enabled to examine into this point of structure and attendant flexibility, which I have done with some care.

It is well known that itacolumnite is the accompaniment, and often the matrix, of the diamond; hence the interest which attaches to its peculiarities, as it would seem in some way to be connected with the occurrence or formation of that gem. Detecting dark coloured grains in it, Dr. Wetherill considers them to be black diamonds, and doubtless he is correct in his supposition, but with this portion of his paper I do not desire to deal at the present time. It is with regard to the structure of the sandstone, whereby it becomes flexible to the remarkable degree so evident when thin slabs are examined. The stone is plainly laminated, and has clearly been thrown down beneath water, it being readily cleavable into more or less distinctly marked laminae.

Almost universally the flexibility is attributed to the presence of mica, but the brighter-coloured specimens which I have examined contain no mica, and yet possess the property of being readily bent to a very marked degree. Even in the red-tinted specimens there are large portions in which no mica is found. Dr. Wetherill says, that by examining the itacolumnite by means of the microscope, he has been enabled to ascertain that the "flexibility is due to small and innumerable ball-and-socket joints which exist throughout the mass of the stone very uniformly. Each joint permits a slight movement which is always greater in one direction." Now, I must say that, though I have come to the investigation prepared with considerable faith, yet, after many careful examinations, I was never able to force my imagination to the extent of getting it to show me anything resembling ball-and-socket joints. The examination need not always be made of the opaque sandstone, but portions can be roughly crushed and mounted in Canada balsam, so that light may be transmitted through them, and the mode of their interlocking plainly made evident. The fact is that the rock is made up of small, broken, irregular masses of transparent sand, which evidently have not been carried any great distance by water, as their sharp edges have not been at all abraded, but, on the contrary, remain, but they have evidently been broken off from a rock which had a conchoidal fracture, they being little plates of extremely irregular outline. Thus, when they settled in the liquid in which we can suppose them to be thrown down, they naturally, for the most part, distributed themselves with their greatest axes in the same direction, and hence the lamination and cleavage of the rock itself. We can readily understand that in such a rock, if the particles were not strongly held together, that they would possess a certain amount of motion one over the other, and this motion would be most marked in a direction at right angles to the lamination, which is the case. But, also, such a rock would not be elastic, only flexible, and gradually, after several times bending, be broken. Such is exactly the case with itacolumnite. In fact, any one possessing a microscope and a fragment of this rock can readily verify my observations, and demonstrate that Dr. Wetherill's proposed name of articulite

* From the *Proceedings of the Lyceum of Natural History, New York.*

is inappropriate for itacolumnite. In conclusion, I would mention that grains of the crushed rock, when put up in Canada balsam, become very beautiful objects for examination by means of the micro-polariscope, exhibiting a gorgeous display of colours when the interposing selenite film is used.

POTASH SALTS FROM SEA-WATER—BALARD'S PROCESS.*

By J. LAWRENCE SMITH.

THIS is another mineral source of potash salts, and it was first devised by Balard some sixteen or eighteen years ago, and has been carried on successfully for many years, but is now seriously interfered with by the supply from the new source of potash in the deposits of potash compounds called "Sylvine" and "carnallite," found occurring in the rock-salt mines of Stassfurt.

By Balard's method the potash salts are obtained in treating the mother-liquor of sea-water salt works, which we may regard as essentially composed of chloride of potassium, sodium and magnesium, and sulphate of magnesia. The object in view is to bring all the sulphuric acid into combination with the soda, and then to obtain, by separate crystallisations, the chloride of sodium, the chloride of potassium, and the chloride of magnesium; the last, being of but little practical value, is allowed to run to waste. The means used to accomplish the results are altogether physical, namely, the abstraction of heat by natural or artificial means. It is based on Scheele's observation, made a great number of years ago, that if a mixture of chloride of sodium and sulphate of magnesia in solution be reduced below freezing point, a double decomposition takes place, and crystals of hydrated sulphate of soda are formed, and chloride of magnesium remains in solution. The separation of the mixed chlorides is made by boiling and cooling the mother-water freed from the sulphate of soda. The original process of Balard was much improved by M. Merle, who employs an artificial cooling process. The following is a detailed description of his process, as communicated by him to the chemical reporters of the London Exposition in 1862.

The process may be shortly defined to consist in the further concentration of concentrated sea-water by exposure to a low temperature, artificially produced. The degree of concentration requisite to fit sea-water for treatment by this process is 1·24 sp. gr., (28° B.) at which point of concentration sea-water deposits about four-fifths of the culinary salt contained in it.

This degree of concentration is obtained by the ordinary process of evaporation on the ground as practised in the manufacture of common salt, of which the ample crop obtained repays this preliminary operation. The mother-liquor which remains is the raw material of the new process. It is stored in large covered tanks, and from this point forward it undergoes no further exposure to dilution by rain, or to absorption by the soil. It is withdrawn from the ordinary operations of the salt gardens, from which M. Merle borrows the one first step—concentration of 1·24 sp. gr. (28° B.) As, however, this degree of concentration is found to be a little beyond the density most favourable to the next stage of the operation, ten per cent of pure water is added to the liquor in the tanks. Thus prepared, the concentrated sea-water is next passed through refrigerating vessels, which are constructed on Mr. Carré's principle, and which cool it to 18° C. This artificial refrigerator causes the desired double decomposition to take place between the sulphate of magnesia and chloride of sodium, sulphate of soda being deposited by the water as it passes through the machine, and chloride of magnesium being carried away in solution.

The process is continuous. The water passes constantly in at one end of the apparatus and out at the other, and the deposited sulphate of soda is continuously withdrawn from the apparatus by a chain of buckets. This salt is speedily freed from mother-liquor by a centrifugal hydro-extractor, and is finally dried in a reverberatory furnace. The utility of the above-mentioned dilution of the tank liquors is now made manifest. If cooled down while at their original density (28° B.) they would let fall much hydrated chloride of sodium, along with the sulphate of soda, to the detriment of its purity and value. But in consequence of the dilution the culinary salt remains dissolved, together with potassic and magnesian chlorides, in the mother-liquor which flows away from the machine.

This mother-liquor has now to be treated for the recovery of the salts it holds dissolved. For the recovery of the culinary salts the mother-liquor is made to flow from the cooling machine directly into boilers like those used in refining rock salt. In these it is boiled down to 1·331 sp. gr. (36° B.), by which time it has deposited nearly the whole of its common salt in a fine powder, which, when dried in a centrifugal machine, equals for purity the best English refined salt. It only remains now to recover the chloride of potassium still dissolved in the hot liquor, which, for this purpose, is poured forth to cool in extensive shallow coolers formed of concrete. Here it soon deposits the whole of its potash as a double chloride of potassium and magnesium. This deposit (a kind of artificial carnallite) is collected, and the magnesian chloride is eliminated therefrom by adding to the mixed mass half its weight of fresh water. This dissolves the whole of the more soluble magnesian chloride, but only one-fourth of the potassic chloride. Three-fourths of the potash are thus obtained as a chloride, containing only one-tenth of extraneous saline matter; the remaining fourth, dissolved with the magnesian chloride in the wash-water, is returned to the boilers.

This capital process works with the utmost ease and regularity. The energetic action of the artificially lowered temperature not only dispenses with the successive eliminations which form the basis of M. Balard's method, but causes the double decomposition to take place with such intensity that the mother-liquors retain but a small proportion of sulphate of magnesia, and lend themselves with ease to the further treatment for obtaining the potash salts. Thus, when the liquid is heated in the boilers, nearly the whole of the chloride of sodium separates without carrying down with it any potash; and when the double chloride is deposited by the subsequent cooling, no potash is left in the waste liquor. The whole of the potash is thus precipitated as double chloride; and this salt being very pure, nothing more is required, in order to obtain separately the chloride of potassium, than to wash out the chloride of magnesium with cold water, and to dry the residue in the centrifugal machine. A very remarkable feature of M. Merle's process is the great facility with which the chloride of sodium is obtained in a finely divided state by ebullition in the boilers. If the liquor of 1·24 sp. gr. (28° B.) were boiled down without previous elimination of the sulphate of magnesia by the above-mentioned cooling process, crusts would form on the bottom of the boiler to such an extent as to hinder the operation greatly, if not entirely to stop it. But the double decomposition which takes place under the influence of cold, by depriving the liquor of sulphate of magnesia, and rendering it rich in chloride of magnesium, changes these conditions. Indeed, the liquor thus treated may not only be boiled down without the formation of the strongly adhering earthy deposits which would otherwise appear, but it does not even produce the slight crusts which form during the refining of rock salt; so that the preparation of the refined salt is carried on under very favourable conditions. Ease and regularity are not, however the only characteristics of this process. It is remarkable, also, for the large quantity of saline products which it is capable of yielding. In fact, the salt-work

* From the "Progress and Condition of Several Departments of Industrial Chemistry."

operation being limited to the production of a liquor of 1·24 sp. gr. (28° B.) on the ground, the loss arising from the permeability of the soil is quite insignificant, and not to be compared with the serious waste which results from this cause when the treatment of the liquor in the salt gardens is continued to much higher degrees of concentration, according to the earlier practice. In point of fact, the first stage of the treatment in the salt works, according to the original method, becomes the last stage in the improved plan. The saline water of 1·24 sp. gr. (28° B.) once transferred to the large tanks remains, during all further stages of the process, in metallic vessels; and, as the subsequent operations are conducted without loss, an amount of product is obtained which, when large evaporating surfaces are employed, may become enormous. A cubic metre of liquor at 28° B., which, if no loss occurred, would correspond to 25 cubic metres of seawater, but which, in consequence of the loss occasioned by infiltration, is equivalent to 75 cubic metres of seawater, yields, when treated as above described, 40 kilogrammes of anhydrous sulphate of soda, 120 kilogrammes refined culinary salts, and 10 kilogrammes of chloride of potassium.

LIQUEFACTION OF CYANOGEN FOR LECTURE EXPERIMENTS.

By Dr. A. W. HOFMANN, F.R.S.

TAKE a piece of combustion-tube about 30 centimetres long, and sealed at one end; at the open end, fix, by means of sealing-wax, a brass cap fitted with a well made brass tap, furnished, in the axial direction of the tube, with a corrugated hose socket. In order to remove the air from this apparatus, a glass tube of narrow diameter is made to pass through the opening of the stopcock into the combustion tube, and carried down to the sealed end thereof; cyanogen gas is conducted through this narrow tube into the apparatus until the gas issuing from the brass socket exhibits, on being ignited, the genuine characteristic cyanogen flame; the narrow glass tube is then withdrawn, and the stopcock shut. The cyanogen gas condensation apparatus consists of two strong flasks, each of a litre capacity, and furnished, at or near the bottom, with tubulatures; these flasks are connected together by means of strongly-made india-rubber tubing enclosed in a stout canvass hose, and 1½ metres in length. One of these flasks is placed somewhat higher than the other, in such a manner that, if the lower is filled with mercury up to the neck, this metal rises in the other flask above the lateral tubulature. In the neck of the flask filled with mercury (lower flask), a perforated cork, carrying a glass tube bent twice at right angles, is inserted, and the cork is fastened to the neck with thin iron wire. The glass tube ought to have the same diameter as that of the brass hose socket, and, like that, should also be corrugated. The glass tube is next connected with a cyanogen gas yielding apparatus, best constructed for this purpose of a piece of combustion-tube, connected with a contrivance for condensing the mercury, filled with cyanide of mercury, and placed in a combustion furnace. By gradually lowering the empty flask, which has been placed highest, the other flask, which contains mercury, becomes gradually filled with cyanogen gas, the mercury running off. The first-mentioned condensation-tube apparatus is next placed in a freezing mixture, consisting of ice, common salt, and some chloride of calcium, yielding a temperature of -25°. The cyanogen-yielding apparatus having been first removed, the glass tube is connected with the brass hose socket of the condensation apparatus, kept in the freezing mixture, by elevating the litre-flask filled with cyanogen gas, and causing the mercury it at first contained, and which had run into the other empty litre-flask, to run into the flask containing the cyanogen gas; that gas is forced into the condensation apparatus, the stopcock of which is closed;

immediately after, the flask which contained the cyanogen gas is filled with mercury again. The condensation apparatus, having been disconnected from the flasks, is taken out of the freezing mixture, and will be found to contain about 5 c.c. of liquefied cyanogen, which keeps unaltered for weeks, and can be experimented with by means of the stopcock fitted to the apparatus.—*Berichte d. ROYAL INSTITUTION OF GREAT BRITAIN.

Notes of a Course of Seven Lectures on Electrical Phenomena and Theories. By Professor TYNDALL, LL.D., F.R.S.

(Continued from p. 106.)

Magneto-Electricity: Induced Currents.

274. In a conductor near to, but not in contact with, a voltaic circuit, a current is aroused when the circuit is established. When the circuit is interrupted, a current is also aroused in the conductor.

275. Thus, supposing the voltaic circuit to be bent into the shape of a ring; and that a second ring, not in the circuit, is placed near the first: at the completion, and at the interruption of the circuit, a current will run round the second ring.

276. The two currents in the second ring are called *secondary currents*. They are of momentary duration. They impart, in passing, a shock to a magnetic needle round which they are sent, and by the motion of which their existence is demonstrated. But they vanish immediately, being quenched by the resistance of the ring and converted into heat.

277. These two momentary currents flow in opposite directions through the ring. The secondary current, excited on making the circuit, is opposed in direction to the primary exciting current; that started on interrupting the circuit flows in the same direction as the primary.

278. These secondary currents are called *induced currents*. They were discovered by Faraday in 1830, and described by him in his Philosophical Papers for 1831.

279. If, instead of employing a single ring, we make use of an electro-magnetic helix, every coil of the helix will furnish its quota of current, and the sum total of effect is much greater than when only a single ring or coil is employed.

For the following experiments, two flat spirals, each formed of covered copper wire, are used.

280. One of the spirals is laid flat upon a table, its two ends being connected with a galvanometer; the other spiral is connected with a voltaic battery, with which the connection can be established or broken at pleasure. Let us call this the *inducing* or *primary* spiral, and that connected with the galvanometer the *secondary* or *induced* spiral.

281. Laying one spiral upon the other, on sending a current through the primary, the needle of the galvanometer is suddenly driven aside by the current induced in the secondary; but the force which acts upon the needle passes away in an instant, the needle returning to its first position.

282. On interrupting the current the needle also receives a shock, being deflected in the opposite direction. It thus declares the existence of a second temporary current in the secondary spiral. The directions of these two currents, with reference to that of the primary, have been already indicated (Note 277).

283. Holding the secondary spiral at a distance from the primary with the current flowing through the latter; on causing the secondary spiral to approach the primary, a current is aroused; this current ceases the moment the motion towards the primary ceases.

284. On withdrawing the secondary spiral from the primary, a current is also aroused; this current also ceases the moment the motion of withdrawal ends.

285. The current excited by approach is opposed in direction to the primary; the current excited with withdrawal is in the same direction as the primary.

286. Two electric currents flowing in the same direction attract each other; if they flow in opposite directions they repel each other.

287. Hence, to make the secondary spiral approach its primary, we have to overcome a *repulsion*; while to withdraw the secondary from the primary we have to overcome an *attraction*. Thus, in order to produce these induced currents, we must expend mechanical force.

288. The force thus expended appears as heat in the secondary wire after the cessation of the induced current. It is the mechanical equivalent of that heat.

289. The approach of a magnetic pole to the secondary spiral and the withdrawal of the pole from the same spiral also arouse induced currents. But, as before, it is only during the periods of approach and withdrawal that the current appears.

290. Thus by the mere motion of a magnet, and without any battery or machine, electric currents may be produced.

291. Every change of the magnetic condition of the space near a secondary coil or within it produces an induced current in the coil. If the change be an augmentation of magnetism, the current is in one direction; if it be a diminution of magnetism, the current is in the opposite direction.

292. When a long secondary coil surrounds a primary coil with a core of iron, by breaking and making the circuit of the primary in rapid succession, a series of powerful discharges may be obtained. An automatic apparatus is usually employed to make and break the circuit.

293. Such induction coils have been constructed with great skill by Ruhmkorff, and are, therefore, sometimes called Ruhmkorff's coils. Mr. Apps has recently produced induction coils of astonishing power.

294. The power of a coil depends mainly on the perfection of the insulation of its coils. The induced currents in a Ruhmkorff's coil may possess thousands of times the electro-motive force of the primary which excites them. They are able, for example, to overleap as sparks distances thousands of times greater than that possible to the primary,

Relation of Induced Currents to the Lines of Magnetic Force.

Rotatory Magnetism.

295. The foregoing phenomena and principles were all laid bare by Faraday. He also established most important relations between his induced currents and the lines of force surrounding a magnet. (See Note 25).

296. He proved that when a conductor moves *along* the lines of force no induced currents appear; but when it moves *across* the lines of force such currents are generated.

297. He proved, for example, that when a metal disk is caused to rotate so as to be tangent to the lines of force, no current appears; while when the disk, in its rotation, *cuts* the lines of force, currents flow along the disk, from the centre to the circumference and from the circumference to the centre. Closed circuits are thus established in the disk.

298. This, in fact, is the "Magnetism of Rotation," discovered by Arago in 1820, which received complete explanation at the hands of Faraday.

299. Faraday showed that the lines of force of terrestrial magnetism suffice to produce induced currents when they are intersected by the rotating disc. In fact, all the effects of magneto-electric induction may be obtained from the magnetism of the earth.

300. When a conductor rotates round an axis which is parallel to the lines of force, it experiences simply the resistance due to the friction of the air; but if the axis of

rotation be transverse to the lines of force, the rotation is retarded by the interaction of the magnet and the induced currents.

301. This retardation may become so powerful as instantly to arrest the rotation. If, for example, a cube or sphere of copper suspended from a twisted string be caused to spin, by untwisting, between the poles of an unexcited electro-magnet, it experiences the retardation due to air friction only; but, on the superposition of the magnetic force, the rotation is suddenly arrested. Faraday also showed that in passing a plate of copper rapidly to and fro between the magnetic poles you seem to be cutting cheese, though nothing is visible. It is as if pure space were a kind of solid.

302. If by mechanical means the conductor be compelled to rotate or to move to and fro between the excited poles, it will be heated. Joule first demonstrated this; but a very striking demonstration of it was given by Foucault, who heated his celebrated gyroscope in this way. The heat is readily rendered sufficiently intense to melt fusible metal. Between the unexcited poles no effect of this kind is produced.

303. The repulsion set up by induced currents between the helices and the moving masses of iron in an electro-magnetic engine, would of itself limit the practical application of electricity as a motive power. Nevertheless, though such engines speedily reach the limit of their action, the conversion of molecular force into mechanical effect may be rendered far more perfect than in the case of the steam-engine.

The Extra Current.

304. If the secondary coil of a Ruhmkorff's machine have its ends united, the secondary circuit being then complete, the spark obtained in breaking the primary is small. On separating the two ends of the secondary the primary spark is instantly augmented.

305. The diminution of the spark is due to the reaction of the completed secondary circuit upon the primary. When the secondary circuit is interrupted, this reaction ceases.

306. The primary circuit in its turn can, when complete, react upon the secondary. It is complete whenever contact is made by the automatic contact-breaker. A great enfeeblement of the secondary current is the consequence. When the primary circuit is interrupted, the reaction does not exist; there is no enfeeblement, the full power of the secondary being developed. It is on this account that in Ruhmkorff's coil we obtain discharges in a single direction only, instead of discharges alternating in direction.

307. The reaction here referred to connects itself with what is called the *extra-current*.

308. When a current is sent through a single primary coil, the primary current excites in the wire which carries it, a secondary current opposed in direction to the primary. The primary arouses an antagonist in its own path, which, however, immediately disappears.

309. When the primary circuit is broken, a secondary current of momentary duration and having the same direction as the vanishing primary, is evoked in the coil.

310. Each of the two currents evoked in the primary circuit itself, at the commencement and at the cessation of the primary current, has been called by Faraday an *extra-current*.

311. The spark obtained on breaking the primary circuit is augmented in brilliancy and power by the extra-current.

312. If a second circuit be associated with the primary; if, for example, two covered wires are wound round the same reel; on making one of them a primary circuit, we have the brilliant spark due to the extra-current, as long as the ends of the second coil remain unconnected.

313. But the moment they are connected the extra-current in the primary circuit disappears; there is an instant reduction in the brilliancy of the spark.

314. This is an example of the reaction referred to in

Note 304. By the closing of the secondary circuit the extra-current is formed in it instead of in the primary one. Here, in fact, the extra-current becomes an ordinary induced current; it is only so long as it remains in the primary circuit that its distinctive name is applied to it.

(To be continued.)

NOTICES OF BOOKS.

Saggio di un Corso di Fisica Elementare, Proposto alle Scuole Italiane. Da GIOVANNI LUVINI, Professore di Fisica Nella R. Militare Accademia di Torino. Quarta Edizione. Torino: 1868.

WHILE two of the most scientific nations of the world are engaged in a murderous strife, at which humanity shudders and the best intellects recoil, it is pleasant to hear the voice of Science from a land to which Science already owes much, and may look forward to peaceful conquests to which she will owe more. If war develops the manhood and the intellect of a country, it cannot be said to be an unmitigated evil, and there is much to encourage the hope, that Italy, made free and united by means of war, has awakened from the long torpor which lay upon her while she was divided and enslaved. There is hope for a nation when her schools are active, and a treatise on Physics of 750 pages has already reached a fourth edition and is used as a text-book by young Italy.

A few years ago we noticed in these pages the address of the President at the opening of the second session of the College of Chemistry at Naples,* in which the backward condition of Italy, consequent on years of political misrule, was feelingly adverted to, while science was in as deplorable a condition as political liberty. In another critical notice we gave a specimen, on the authority of Melloni, of the kind of scientific teaching permitted under Austrian and Bourbon rule.† Certainly, if the work before us may be taken as an exponent of Italy's progress during the last three years, she has indeed made rapid advances in scientific culture, for this Treatise on Elementary Physics would do honour to any country however advanced.

It must not, however, be forgotten that a nation that lives on the recollection of her former freedom and greatness, and never willingly consents to servitude and oppression, has a wonderful elasticity in recovering her rectitude when the weight of tyranny has once been shaken off. Such is Italy, and now that she is happily free and united, she not only looks back to her former fame, but forward to support and maintain her old renown. Hence, in the treatise before us, the scientific glories of Galileo, Torricelli, Venturi, Volta, Melloni, Matteucci, and a host of others, not forgetting modern workers, are quoted on every opportunity with that honest pride which a man feels when he can say "I too am a countryman of Galileo!"

This frequent reference to Italian *savans* gives a peculiarly national tone to the work, and in many respects increases the interest we feel in it. It is too much to expect that the order of scientific freemasonry will ever be established in which all the labourers in the field of Nature shall regard each other as Brethren; the stronger claims of race will prevail, and the *savan* will always be ready to accept the formula, "*My country first—even Science must yield to that.*" *Patriæ fumus igne alieno luculentior.*

We can best illustrate the national feeling to which we refer by quoting the following passage, in which it seems odd to miss the name of Francis Bacon.

After some remarks on the defects of the peripatetic philosophy, the author says:—"It required all the power of a Leonardo da Vinci, of a Benedetti, and, above all, of a Galileo, to recall the attention of the studious to the methods of observation, experiment, and calculation. From the moment when it came to be generally understood

that, in the physical sciences, Truth, rather than Authority, must be the guide, there arose a whole generation of explorers of Nature. A vast variety of new phenomena were discovered, which, by their reciprocal action, corrected, while enlarging, the sphere of observation, thus laying the foundation of productive theories, which, in their turn, being successively corrected and renewed, assisted in the discovery of new facts, having served, and still serving, to colligate things apparently unconnected, thereby facilitating the study, while improving the stature, of the body of science."—Page 82.

This pride in her scientific men (from which England is comparatively free) has many advantages. It is not only a stimulus to scientific workers, but it assists scientific work. When, instead of leaving the works of men of genius in dusty oblivion on the shelf, the scientific teacher shows himself to be well acquainted with the scientific literature, at least, of his own country, his class, unconsciously adopting the habits of thought of the teacher, begin to cherish the memory, and to peruse the works, of their countrymen who have enlarged the boundaries of knowledge. The aid thus given to the history of discovery is illustrated, in a remarkable manner, by an extract from Galileo, which we meet with in the work before us at page 285. We had never supposed there was any doubt as to the authorship of Chladni's sound figures, and yet we read that Galileo, while scraping a plate of brass, noticed that the dust on the plate arranged itself in equidistant parallel streaks, and, by varying the notes, the figures also varied. Among the notes produced were two, which, by comparison with a viol, were found to differ by a fifth. Measuring the spaces formed by the dust lines, in the two cases, he found 30 of the one equal to 45 of the other, "*quale veramente è la forma che si attribuisce alla diapente.*"

The treatise before us, in addition to the usual subjects of Physics, contains an outline of the Mechanical Sciences, including Astronomy, of the Atomic Theory, and numerous details which we now include under Chemical Physics. The chapters on Cohesion and Adhesion are remarkably well done. The author is not afraid to question certain received doctrines, and to express his belief that the theory of capillary action, as propounded by Clairaut, La Place, and Poisson, represents some clever applications of the calculus rather than of Nature. His own demonstration of capillary action is neat and clear. He also gives some of the latest details respecting surface tension, and copies the figures of Plateau, Van der Mensbrugghe, and Tomlinson, and gives some new figures of his own.

Thus, while the book is essentially Italian, in consequence of its numerous references to Italian *savans*, past and present, the author, nevertheless, looks out of Italy, and does not forget that there are successful *savans* elsewhere.

But the work has yet other claims to respectful attention. The author does not fall under the reproach, implied in Davy's remark on Berzelius, "He is only a chemist!" Prof. Luvini occasionally indulges in metaphysical subtleties, which are, among other benefits, so far useful, in reminding us of the narrow limits of our powers, that when we seek for a definition of the matter on which we work, or of the mind by which we work, we are reduced to the humiliating conclusion, that "as matter is the mysterious something which excites the mind to feel, so mind is the mysterious something which feels and thinks."* There is also an occasional touch of sarcasm in what may be called the bye-play of the lecturer, when, as if speaking to himself, or thinking aloud, he remarks—say, in reference to Dutochet's mysterious epipolip force—"Fine times those, when the creation of a name was deemed equivalent to the exposition of a fact!"—Page 226.

We also especially admire the author's love of poetry,

* CHEMICAL NEWS, vol. xv., p. 238.

† *Ibid.*, vol. xv., p. 185.

* See Mill's "Logic," ch. iii., § 8.

which gives a charm to his style and a breadth to his teaching. Such teaching must have the best effect on the young men of his class who come to learn physics (and it must be their own fault if they fail to do so), and while acquiring this knowledge are reminded by various side touches that the literature, the art, and the science of a country are under mutual obligations to each other.

It is difficult to select a passage that will convey an idea of the work as a whole, or even of the author's style, unless it could be given in the beautiful language of the original, for our author, in common with the French *savans*, seems unconsciously to adopt the maxim that scientific teaching is improved by a clear and graceful style: we will, however, venture to translate a passage from the end of the chapter on Chemical Actions.

"We were formerly accustomed to say that the power of the chemist was limited to the artificial formation of inorganic bodies only. The progress of organic chemistry has already swept aside this limitation. But, in truth, all chemical products proceed from the hand of Nature; all that man does is to bring together the elements destined to mutual reaction. Whether we decompose water, oxidise zinc, crystallise sulphur, or fuse gold, we do nothing more than what Nature herself does in bringing about the same results. Is it not by realising the necessary conditions that the gardener produces the immense variety of plants and the grazer the best animals? or, as the poet well expresses it,—

'If in the maw of the serpent the juice is transformed into poison,
Still it becomes sweetest honey when hid in the bag o' the bee.'

"The whole difficulty consists in knowing and being able to dispose of matter in such a manner as to bring about those reactions that lead to the changes we are in search of."—Page 262.

The scientific formulæ given in the work are of an elementary character, but sufficient to redeem it from being superficial, which some so-called popular treatises are. We may further remark that the author is himself an original worker, or he could not have produced so excellent a treatise. A translation of a paper by Professor Luvin on the viscosity of liquids will be found in the September number of the *Philosophical Magazine*.

C. T.

Highgate, N., August 25th, 1870.

Heat a Mode of Motion. By JOHN TYNDALL, LL.D., F.R.S., &c., Professor of Natural Philosophy in the Royal Institution of Great Britain. Fourth edition. London: Longmans, Green, and Co., 1870.

THE very fact of the fourth re-issue of this work is an undeniable proof of the excellence of its contents. The author has bestowed upon this edition additional care, and enriched it with some account of his recent researches on the chemical reactions of light, considered from a dynamical point of view. In the former editions the relations of gaseous matter to the longer waves of the spectrum were developed; in this one the relations of the same form of matter to the shorter waves are also submitted to experimental treatment, the two lines of inquiry being united by the conception of molecular motion, which is common to both. The bearing of some of the results on two of the great questions of meteorology—the Blue Colour of the Sky, and the Polarisation of its Light—is likewise explained and pointed out. The author has also added a hypothesis regarding the Constitution of Comets, and a few remarks on the Polarisation of Heat. This edition is greatly enlarged, its contents are rendered more interesting, and are made complete up to the present date. The eminent author deserves the sincere thanks of all who can appreciate, and we hope very many do, the insight he is gradually acquiring into this department of natural science. As is generally the case with books published by this firm, the work is highly commendable for its typographical execution and excellent engravings and woodcuts.

CORRESPONDENCE.

TEMPERATURE AND HEATING-POWERS OF FLAMES.

To the Editor of the Chemical News.

SIR,—In your last number Professor Wurtz replies to my criticism on the paper of Professors Wurtz and Silliman on the "Calorific Powers or Effects of Gases."

Professor Wurtz first of all charges me with inattention to his paper, and with confusion of ideas—in suggesting that by the term "heating effect of a gas," he really means the "flame-temperature"—and then, in the last paragraph, acknowledges that the numbers given in my note (which are calculated flame-temperatures), are precisely what he has designated as calorific powers or effects. The term "calorific power" is a term in common use, and to be carefully distinguished from "calorific intensity," which is synonymous with "flame-temperature." Professor Wurtz certainly uses the term "calorific effect" for the numbers calculated by Bunsen's formulæ, which are really the theoretical flame-temperatures, whereas "calorific power" has always been used to mean the quantity of heat produced by the combustion of a given weight of the substance. It is used in this sense by Percy in his "Metallurgy," and indeed is employed in that sense by Professor Wurtz himself in part of his paper.

But the real point at issue between us is not a question of terms at all, but of facts, and in order that this may be clearly understood, I must beg permission to quote from the original paper somewhat at length. Professors Silliman and Wurtz write:—

"The admirable researches of the great gas-chemist, Bunsen, of Heidelberg, placed in our possession, some years ago, the means of computing, at least with approximate accuracy, the heat of flames of gases of known compositions. Few, however, have properly and successfully applied Bunsen's method in practice. We consider it quite time that these methods should be introduced to the knowledge of gas-engineers, in forms available to them.

"Bunsen's formulæ for these computations are based upon the actual experimental determinations of the total amounts of heat developed by the combustion of different pure combustible gases with pure oxygen made by Favre and Silbermann, and upon Regnault's determinations of the specific heats of gaseous products of combustion.

"It is not to be maintained that Favre and Silbermann's numbers are strictly correct, but they are doubtless approximate, and at least proportionately correct among themselves; at any rate, they are the best data we have. Those employed here are included in the following table. They are usually given in the text-books for equal weights of the gases; but we have reduced them to the standard of equal volumes also, as more suitable to our present purpose. This reduction is made simply by multiplying the equivalents for weights by the densities as given in the third column.

TABLE I.

	Total calorific equivalents		Densities on scale of hydrogen = 1.
	Of equal weights.	Of equal volume.	
Carbonic oxide	34,462° C. ..	34,462° C. ..	1.0
Hydrogen ..	2,403° ..	33,642° ..	14.0
Marsh gas ..	13,063° ..	104,504° ..	8.0
Olefiant gas ..	11,858° ..	166,012° ..	14.0

"The meaning of this table is simply that equal weights of water would be heated by the several gases to temperatures proportional to the numbers in the first column when equal weights of the gases are burned, and propor-

tional to those in the second column when equal volumes are burned.

"A cursory glance at the figures in the second column of this table might seem to justify the notion hitherto entertained by many of the comparatively low calorific powers of hydrogen and carbonic oxide; and it was doubtless as a consequence of such a comparison as this that statements have been put forth and widely accepted among American gas-engineers to the effect that the weight of water heated from the freezing to the boiling-point by 1 cubic foot of the four main components of illuminating-gas, respectively, is as follows:—

Hydrogen	2.22 lbs. water
Carbonic oxide	2.16 "
Marsh gas	6.17 "
Olefiant gas	10.74 "

"The figures here being obviously about in the same ratio as those in the second column of Table I. Several most grave errors, however, are here involved. To get at the true relative calorific effects of the above gases, when burned in the open air, in heating water below its boiling-point, deductions must be made, not only for the specific heats of the products of combustion of the gas, but also (more important still) for the specific heat of the nitrogen of the air required to burn the gas. In fact, when we consider that, for each volume of oxygen required to burn a given volume of a gas, about four volumes of nitrogen must be heated up to the temperature of the flame, it becomes easy to conceive, what is actually the fact, that, within certain limits, the waste of heat due to this cause alone counterbalances altogether the advantage that would be supposed to result from the crowding of combustible matter into so condensed a form as in the illuminating hydrocarbons. An inevitable result of our investigations of this matter is that the heating powers of the flames of pure hydrogen and pure olefiant gas, even when used to the greatest advantage, to heat water below its boiling-point are almost or quite identical."

Now, I venture to assert that the numbers just quoted, in which, according to Professor Wurtz, "several most grave errors are involved," are substantially correct—that the specific heats of the products of combustion and of the nitrogen of the air required to burn a gas have nothing whatever to do with the maximum calorific effect of the gas, and that, instead of the powers of the flames of hydrogen and olefiant gas to heat water below its boiling point being identical, olefiant gas will be always nearly five times as effective as the same volume of hydrogen burnt under the same circumstances.

Professor Wurtz admits the justice of my objection to his statement that the heating effect of olefiant gas is ever lower than that of carbonic oxide, if the combustion take place in pure oxygen, but affirms that it has no force if the combustion take place in air.

I must plead guilty to want of precision in not clearly stating that I was speaking of combustion in air (my statement that the flame-temperature of carbonic oxide is higher than that of olefiant gas is not even true if the combustion take place in pure oxygen), and in not pointing out that the reason why the flame of olefiant gas in air is colder than that of carbonic oxide in air, although the quantity of heat produced by its combustion is so much greater, is not only the latent heat and the high specific heat of the steam produced in the former case, but also the larger quantity of nitrogen, which is one of the products of combustion. But, surely, whatever the products of combustion are, when they are made to give up their heat to water they must give out exactly the same quantity of heat which was required to raise them to the temperature which they possessed; and, thus, the effect of a gas in heating water will be the same, whether it be burnt in oxygen or in air, and will be correctly measured by the calorific equivalent (of equal volumes) given in the table quoted above. The number for olefiant gas being nearly five times that for hydrogen, my state-

ment is justified that the flame of olefiant gas is nearly four times as efficient in heating water below 100° as the flame of hydrogen. Professor Wurtz may object that this is true only if the products of combustion give up all their heat and escape themselves at a temperature of 0° C., which is, of course, impossible. The following results of calculation show that if the products of combustion escape at a temperature above 100° C., olefiant gas is even more than five times as efficient as the same volume of hydrogen.

The combustion in air of	Will raise from 0° to 100° C.	If the products of combustion escape at the temperature
1 lb. hydrogen ..	344.62 lbs. water ..	0° C.
14 lbs. olefiant gas..	1660.012 "	0° C.
1 lb. hydrogen ..	329.1 "	100° C.
14 lbs. olefiant gas..	1593.7 "	100° C.
1 lb. hydrogen ..	184.17 "	1000° C.
14 lbs. olefiant gas..	984.16 "	1000° C.

—I am, &c.,

W. MARSHALL WATTS.

Manchester Grammar School,
Aug. 29th, 1870.

MISCELLANEOUS.

Recent Chemical Appointments.—Mr. T. E. Thorpe, Ph.D., of Manchester, has been elected Professor of Scientific Chemistry at Anderson's University in the room of the late Professor Penny. Dr. Thorpe has for some time held the post of Junior Assistant in the Chemical Laboratory at Owen's College, where his talents and zeal have been fully appreciated. Dr. Debus, F.R.S., has been appointed to succeed Dr. Alfred Swaine Taylor, F.R.S., as Professor of Chemistry at Guy's Hospital Medical School. Dr. Debus is succeeded, as Lecturer on Natural Science at Clifton College, by Mr. G. Farrer Rodwell, F.C.S., whose originality of thought and powers of description, combined with his high scientific attainments, well qualify him for the appointment.

University of London.—The following are lists of the candidates who have passed the recent M.B. and B.Sc. examinations:—*First M.B. Examination (Examination for Honours).*—Organic Chemistry, and Materia Medica and Pharmaceutical Chemistry: First Class. Chas. Atkinson Nankivell, Exhibition and Gold Medal, University College; William Smith Greenfield, University College, and Ebenezer Geer Russell, Guy's Hospital (equal); George Birt, Sydenham College, Birmingham. Second Class. Sidney Coupland, University College; Henry James Benham, University College. *First B.Sc. and Preliminary M.B. conjointly.*—Chemistry: Second Class. Henry Hetley, Prel. Sci., Guy's Hospital; P. Herbert Carpenter, First B.Sc. and Prel. Sci., University College and Royal School of Mines. Third Class. F. John Morton Palmer, Prel. Sci., Guy's Hospital, and Ernest William White, Prel. Sci., King's College (equal); Eugène Créten, Prel. Sci., St. Bartholomew's Hospital, and Thomas King Rogers, Prel. Sci., University College (equal); H. Joseph Firth Groves, Prel. Sci., Guy's Hospital. *Experimental Physics:* Second class. John Landor Lowe, First B.Sc., King's College.

British Association for the Advancement of Science.—The following is the programme of the arrangements for the fortieth annual meeting of the British Association for the Advancement of Science, to be held in Liverpool, commencing on Wednesday, the 14th inst. President-elect—Professor Huxley, LL.D., F.R.S. Vice-Presidents-elect—The Right. Hon. the Earl of Derby; Right. Hon. W. E. Gladstone, M.P., D.C.L. Sir Philip G. Egerton, Bart., M.P., F.R.S.; Sir Joseph Whitworth, Bart., LL.D., F.R.S.; S. R. Graves, Esq., M.P.; J. P. Joule, Esq., LL.D., F.R.S.; Joseph Mayer, Esq.,

F.S.A. Chairman of Local Executive Committee—The Mayor of Liverpool (Joseph Hubback, Esq.) Local Treasurer—Henry Duckworth, Esq., F.G.S. The sections are:—A—*Mathematical and Physical Science* (in the Crown Court, St. George's Hall): President—J. Clerk Maxwell, F.R.S.L. and E.; Secretaries—Prof. W. G. Adams; W. K. Clifford; Prof. G. C. Foster, F.R.S.; Rev. W. Allen Whitworth. B—*Chemical Science* (in the Royal Institution, Moore Street): President: Prof. Henry E. Roscoe, Ph.D., F.R.S., F.C.S.; Secretaries—Prof. A. Crum Brown, F.R.S.E., F.C.S.; A. E. Fletcher, F.C.S.; Dr. W. J. Russell, F.C.S. C—*Geology* (in the Concert Hall, Lord Nelson Street): President—Sir Philip de Malpas Grey Egerton, Bart., M.P., F.R.S., F.G.S.; Secretaries—W. Pengelly, F.R.S., F.G.S.; Rev. H. H. Winwood, F.G.S.; W. Boyd Dawkins, F.R.S., F.G.S.; G. H. Morton, F.G.S. D—*Biology* (in the Reading Room and Lecture Room of the Free Public Library): President—Prof. G. Rolleston, M.D., F.R.S., F.L.S.; Vice-Presidents—John Evans, F.R.S., F.G.S., F.S.A.; Prof. Michael Foster, M.D., F.L.S.; Secretaries—Dr. T. S. Cobbold, F.R.S., F.L.S.; Thos. J. Moore; H. T. Stainton, F.R.S., F.L.S., F.G.S.; Rev. H. B. Tristram, LL.D., F.R.S. E—*Geography* (in the Small Concert Room, St. George's Hall): President—Sir Roderick I. Murchison, Bart., K.C.B., D.C.L., LL.D., F.R.S., F.G.S.; Secretaries—H. W. Bates, Assist. Sec. R.G.S.; Clements R. Markham, F.R.G.S.; Albert J. Mott; J. H. Thomas, F.R.G.S. F—*Economic Science and Statistics* (in the Council Chamber, Town Hall): President—Prof. Jevons; Secretaries—E. Macrory; J. Miles Moss. G—*Mechanical Science* (in the Civil Court, St. George's Hall): President—Charles Vignoles, C.E., F.R.S., M.R.I.A., F.R.A.S.; Secretaries—P. Le Neve Foster; J. T. King. General and Evening Meetings—Wednesday, Sept. 14: The first general meeting will be held in the Philharmonic Hall, at 8 p.m., when Professor Stokes, M.A., D.C.L., will resign the chair, and Professor Huxley, LL.D., F.R.S., will assume the Presidency and deliver an address. Thursday, Sept. 15: The Mayor's First Reception at the Town Hall. Friday, Sept. 16: Lecture in Philharmonic Hall, at 8.30 p.m., by Professor Tyndall, LL.D.; the Mayor's Second Reception at the Town Hall. Saturday, Sept. 17: Address to Working Men, in Concert Hall, Lord Nelson Street, at 8 p.m., by Sir John Lubbock, Bart., M.P., F.R.S. Monday, Sept. 19: Lecture in Philharmonic Hall, at 8.30 p.m., by Professor Rankine, LL.D., F.R.S. Tuesday, Sept. 20: Soirée in St. George's Hall, at 8 p.m. Wednesday, Sept. 21: Concert in St. George's Hall, at 8 p.m. Thursday, Sept. 22: Excursions to several places. Members requiring Railway Pass Tickets and further information should apply to any of the following Hon. Local Secretaries—Wm. Banister, B.A.; Reg. Harrison, F.R.C.S.; H. H. Higgins, M.A.; A. Hume, D.C.L., LL.D., Municipal Buildings, Dale Street, Liverpool.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, August 22, 1870.

This number does not contain any papers or memoirs relating to chemistry, but, among the few published relating to physical sciences, we notice—

Note on the First Session of the International Committee of the Metrical System, which met at Paris from the 8th to the 13th of August last.—General Morin.—We learn from this paper that twenty out of the twenty-five States which accepted the invitation were represented at this meeting; these States are—The Austro-Hungarian Empire, Chili, Columbia, Spain, Papal States, United States of America, Republic of Ecuador, United Kingdom of Great Britain and Ireland, Greece, Italy, Nicaragua, Peru, Portugal, Russia, San Salvador, Sweden, and Norway, Switzerland, and Turkey. The meeting has appointed—President, M. Matthieu. Vice Presidents—M. Struve, of St. Petersburg; Dr. W. A. Miller, London; M. Henry, Secretary of the Smithsonian Institution, Washington, U.S.; M. Herr, Vienna; General Morin. Secretaries—M. Tresca, Paris, and M. Hirsch, Neuchâtel, Switzerland. The Committee, having fixed upon the programme of their labours, and having appointed sub-committees, has adjourned its meetings *sine die*.

Phenomenon of Choc en Retour observed at Porto-Alegre (Brazil).—M. Laranja Oliveira.—The author writes—One of my servants had to walk home, in the early part of last June, during a violent thunderstorm. When at about 100 metres' from my residence, in the outskirts of this town, and just when a violent flash of lightning appeared, he felt suddenly as if his body was everywhere pricked with needles, his feet were temporarily lamed, and the hair of his head raised upright to such an extent as to oblige him to hold his hat with his hands to prevent it from falling off; close to him (at about 2 metres' distance) he saw, near to the ground, a whitish smoke, which emitted flashes of vivid lightning, it being about midnight. After having recovered, and arrived home, he discovered that a key he happened to have had in his pocket had become strongly magnetic.

August Meteorites of this Year.—M. Chapelas-Coulivier-Gravier.—The author states that this year is exceptional, as regards the scarcity of meteorites seen generally; he next enumerates some of the causes which co-operate to render the observation of the meteorites more difficult, as there are, for instance, cloudy sky and strong moonlight; lastly, the author gives the names of the constellations wherein most of these luminous meteors have been seen during the month above named.

Moniteur Scientifique, No. 328, August 15, 1870.

This number does not contain any original memoirs or papers, but we quote the following from the *brevets d'invention*:—

Improvements in the Manufacture of Animal Charcoal.—MM. Pilon and Co., Paris.—This improvement simply consists in the granulating of the bones previous to their calcination, the result being that the quantity of dust and small (useless for the purposes of the sugar refiner, and of inferior value for agricultural purposes) is very considerably lessened. The bones, of course, have been first boiled, and the fat extracted by proper means.

Manufacture of Sal-Ammoniac Combined with the Production of Peroxide of Manganese.—L. J. Martin.—Of the residues of the manufacture of chlorine, 600 kilos. are mixed with 100 kilos. of ammonia (sp. gr. 0.924). This magma is first somewhat evaporated; and, after the clear liquid has been decanted, it is evaporated to dryness, and then sublimed, while the manganese is slowly peroxidised. The editor of the above-named periodical very properly observes that, although, in theory, such a process might answer, it is, even with small quantities, not of any practical utility.

Girondin Disinfectant.—G. Vigué.—The author mixes, but does not say in what quantities, sulphate of zinc, acetate of copper, carbolic acid, and crystals and essence (sic) of baryta, to be together dissolved in water. No explanation is given as to what essence of baryta means.

Manufacture of Steel Types for Typographical Use.—G. Bauer.—By an ingenious mechanical contrivance, not unlike that in use for making nails, the author converts previously-softened steel wire into types which are afterwards hardened. With a single machine, and a 1-H.P. steam-engine, 35,000 types can be made in twelve hours, while the types thus made are of a superior finish, and cheaper also, on account of the less expense of the steel as compared with the ordinary type metal (usually an alloy of antimony and lead, in the proportion of 1 part of antimony to 4 of lead, with a very small quantity of copper, the latter being usually present in sufficient quantity in what is termed hard lead).

As a curiosity, we mention the following:—

Pomatum for Softening and Whitening the Skin.—H. Freymond.—The author has taken a *brevet d'invention* for a mixture of olive oil, lavender essence, white wax, oil of turpentine, mutton suet, and common carmine. This would, no doubt, do very well for French polish, but the oil of turpentine would render it highly unpleasant, to say the least of it, to those who should apply it to their skin, and especially lips.

Les Mondes, August 18, 1870.

Soluble Vegetable Tar (Sacharolé de Goudron).—A. Roussin.—The author states that he has succeeded in obtaining, by the use of pure sugar, a very useful pharmaceutical preparation to supersede the use of tar-water as made and applied from what is termed in this country Stockholm tar. The preparation is a powder of constant composition, and containing 4 per cent of the real active principles of the tar-water of the Pharmacopœia; it is highly spoken of by M. Gay, a very well known pharmacist, and Director of the pharmaceutical school at Montpellier.

Toselli's Dynamical Refrigerator.—The author describes, and illustrates with woodcuts, a contrivance consisting mainly of a tube wound round a central axis, and movable in a trough partly filled with water, and not unlike the trough in use for grindstones. By the rapid motion of the tube through the water, that fluid enters the tube; while the water which is outside of it evaporates rapidly, and, by that evaporation, causes the cooling of the water inside, which, by the developed centrifugal force, is carried through the windings of the tube, and thus affords means for obtaining a supply of comparatively cold water. The author has found, by experiment, that, even when the initial temperature of the water is 36°, it may be cooled down to 18°; and when a ventilator is simultaneously used, so as to produce a strong current of air upon the convolutions of the tube, and thus accelerate the evaporation, the cooling effect is greatly increased. The speed to be given to the metallic tube is very moderate.

August 25, 1870.

Useful Applications of the Electric Light.—F. E. Paris.—This lengthy paper chiefly treats of the application of the electric light to lighthouses, as signal-lamps on board ships, and also for affording light to narrow channels near the mouth of rivers, and for rendering approach to harbours possible during the night time. The author has experimented with various magneto-electric machines, and gives, in detail, the requisite instructions for the management of electric lights for the purposes above alluded to.

Silver Mine of Potosi.—This mine, situated in the Andes of Peru, is considered the highest mine wrought in the world, as regards its elevation above sea level, which is 3465 metres; while the deepest mine under thesea level is the salt mine of Neusalzwerk (Westphalia), which is 625 metres below the sea.

Composition of Chinese Lacquer-Work.—Dr. Wiederhold.—According to the author, genuine Chinese lacquer-work is done over tin-foil, and consists of a mixture of 2 parts of copal and 1 of shellac, molten together. When fluid, there are added 2 parts of boiled linseed oil; and, after the vessel containing this mixture has been taken from the fire, there are gradually added 10 parts of oil of turpentine. If colour is required, gummi-gutta, dissolved in oil of turpentine, yields yellow, and dragon's blood, dissolved in the same liquid, yields red.

Artificial Ice.—M. Toselli.—The author, writing to the editor of the above-named periodical, states that actual experience has proved that the ice made by the process invented by him withstands the influence of a temperature far above the freezing-point of water better than natural ice, or than any other ice obtained by artificial means; and to illustrate this fact, the instance, properly proved, is brought forward, that a block of ice weighing 20 kilos., made by the author's process in eighteen minutes, and sent off from Paris to Algiers on the 30th of June last, arrived, properly packed, at its destination late in the afternoon of the 5th of July, and the block of ice then remaining still weighed 10 kilos. The loss, by fusion, on a journey through a warm climate in the middle of summer was, therefore, only 84 grms. per hour. 100 kilos. of ice made by the author's process would require, under the same conditions of temperature, 494 days to liquefy it; whereas 100 kilos. of the ice artificially made by the process of M. Tellier, has been found to melt in six days under the same conditions. It appears that M. Toselli's apparatus renders ice very compact.

Journal de Pharmacie et de Chimie, August, 1870.

This number contains the following original papers and essays:—

New Process for the Quantitative Estimation of the Alkaloids of the Cinchona and Calisaya Barks.—P. Carles.—The author begins with giving a review of the different methods hitherto in use for the quantitative estimation of the alkaloids alluded to, which methods may be divided into two main classes—viz., those by which the whole of the alkaloids are estimated together, and those by which only the quinine is estimated. The author's new method is the following:—A fair average sample of the bark to be tested is ground up to a fine powder, and sifted, but any residue left on the sieve is to be pulverised again. 20 grms. of this powder are taken and intimately mixed, in a mortar, with 8 grms. of quick-lime, slaked, just previous to use, with 35 grms. of water. The pasty mass thus obtained is dried on a water-bath. As soon as the mixture has become dry enough to be broken up into small lumps, this is done, and the lumps placed in a funnel-shaped tube, the lower and narrower opening of which is closed by a plug of cotton wool. Chloroform is poured over the mass, a quantity of 150 grms. being sufficient, and the last traces of that fluid are washed off with some distilled water; the larger portion of the chloroform is either evaporated or (as may suit the operator) distilled off on a water-bath, and the residue taken up with from 10 to 12 c.c. of dilute sulphuric acid (1 of acid to 10 of water). This solution is poured on to a previously well-moistened filter, which retains the resinous matters, while a clear liquid runs off. The filtrate is boiled, and, when in full ebullition, ammonia is added to it, so as to leave only a slightly acid reaction; all the sulphate of quinine crystallises out, while the mother-liquor retains the rest of the alkaloids, which may be separated by precipitation and further tested. The author has added to his paper some tabulated results of experiments made by him with the same quantity of bark, and operating with various methods executed carefully, as described by the original authors and suggestors of these methods, in order thus to prove the superiority of his method.

Soluble Iodide of Starch, and its Decolouration by Heat.—A. Petit.—This paper treats on the proper method of preparing a pharmaceutical compound and a syrup of iodide of starch, and on the changes these mixtures undergo by the action of heat. It appears

that the cause of the well-known decolouration of iodide of starch by the application of heat is due to the complete solubility of that compound at a high temperature, and the temporary destruction of the combination existing at a lower temperature between starch and iodine.

Heat Set Free by the Mixing of Two Liquids.—M. Berthelot.—A letter to M. Busay, only containing a series of algebraic formulæ.

Basic and Neutral Bromhydrates of Quinine and Cinchonine.—M. Latour.—The author describes the preparation, for pharmaceutical purposes, of compounds made up of bromide of potassium and sulphate of quinine. Some of these salts so obtained are really chemical combinations which, in their general characters, do not differ from chlorhydrates of quinine.

Experimental Researches on Gold and its Compounds.—J. P. Prat.—The main results of the author's experiments are—That nitro-muriatic acid chlorurises gold in various degrees, and that this depends upon the composition of the acid, the quantity which is applied in reference to the gold, and the degree of heat; that pure gold can be readily and rapidly prepared and obtained in spongy state; that gold can be directly oxidised and salified by oxacids; that there exists a liquid and volatile chloride of gold containing more chlorine than the sesquichloride; that there exists, likewise, a sesquiodide and a carbonate of gold; that there exist two oxides of gold capable of giving a new series of salts; and, lastly, that gold behaves in many instances like some of the other metals.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, No. 5, 1870.

This number contains the following papers and memoirs relating to physico-chemical and collateral sciences:—

On the Landen Sandstone.—J. Moreau.

Determination of the Declination and Inclination of the Magnetic Needle at Brussels in 1870.—A. Quetelet.—A series of tabulated results.

Note on the so-called Natural Pits (Puits Naturels) of the Coal Measures.—MM. Cornet and Briart.—The description of certain hollow and deep faults also met with in some of the cretaceous formations, especially the *Maestricht tufa*, and known locally as geological organs.

Determination of the Exact Latitude of the Tower of the Antwerp Church of Notre-Dame.—A. Boë.—The author has determined this latitude by astronomical observations, and the result arrived at is, that the north latitude of the building alluded to is 51° 13' 14" 98, a figure only differing by 2-100ths from that obtained nearly sixty years ago, by M. Krayenhoff, by geodesical measurement.

Revue Universelle des Mines, de la Métallurgie, et des Travaux Publics de Belgique, No. 3, 1870.

This number contains only the following original papers relating to physico-chemical and collateral sciences:—

Motion of Permanent Gases through Pipes and Tubes.—Dr. Grashof. And—

Agglomeration of Fuel.—A. Habets.—Both papers being continuations of the portions published in previous numbers of this periodical.

Cosmos, August 20, 1870.

Lavoisier Medal.—Upon the report and proposition of M. A. Payen, this medal has this year been granted to M. H. Sainte-Claire Deville, in consequence of the great number of useful researches made by that *savant* in chemistry, and the application these researches have received in practice. Among the subjects enumerated are—Researches on platinum; the industrial manufacture of sodium; the discovery of the hydraulicity of magnesia; the researches on the application of dead and other heavy hydrocarbon oils as fuel for steam-boilers; the dissociation of bodies by heat.

Cause of the Fires of Pine Forests.—F. Schrader.—The author very ingeniously observes that the cause of the very frequent fires of pine forests, in summer time only (large tracts of country in the Départements des Landes and de la Gironde are covered for miles and miles' distance with such forest, and remote from any habitations), is not due, as has been often surmised, to wilful arson or accidental imprudence, but is produced by the action of the concentration of the sun's rays upon the hollow globules of resin which exude from the trees, acting as burning lenses, and becoming inflamed; thus causing the combustion to begin, and, once begun, to spread rapidly, in consequence of the highly inflammable nature of the resinous and turpentine-containing wood.

The Part Gaseous Substances Play in Volcanic Eruptions.—J. Delanoue.—The main point of interest contained in this lengthy paper is, that hydrogen gas plays the chief part in the volcanic eruptive phenomena.

Man of the Tertiary Period.—M. Raulin.—The author states that, until the contrary be proved, he thinks that, just as there have been in the five successive faunas, five distinct species of rhinoceros, so the genus *Homo* may have been represented in each succeeding

fauna by species which become gradually more intelligent than their predecessors had been.

Draining of the Dombes, and their Conversion into Fertile Fields.—M. Givord.—By Dombes is understood a portion of the Département de l'Ain, comprising a surface of 90,000 hectares, situated between the rivers Rhone and Saone. In the 13th century this country was a most fertile plain, but about that time the inhabitants, for some reason or other, not specified, commenced making pools of water, now covering 11,000 hectares (the likelihood is that, as in the case in some parts of Holland, peat has been dug, and, by this process, shallow lakes of great surface have been formed); and, as a consequence, malaria spread among the inhabitants, causing, according to the author, such ravages as to sweep away even towns which once had 4000 inhabitants, to reduce the average duration of human life to twenty-one years (only half that of the rest of France), and to impoverish the scanty population. The author enters into details as to the draining of the pools alluded to, but his chief aim is to prove how the work of man may influence his own physical, as well as mental, well-being, and how necessary it is to carry out the drainage of this region.

International Conference on the Prototype Metre. Dr. O. Struve, Director of the Observatory of the Pulkowa; M. Wilder, Director of the Physical Observatory and Museum at St. Petersburg; and M. Mohn, the Director of the Meteorological Institute of Christiania, have arrived in Paris, for the purpose of taking part in the international conference on the metre and the metrical system generally.

August 27, 1870.

Luminous Phenomenon.—Dr. Roussille.—The author states that, while making a geologico-botanical excursion on the Mount Pilat (Cévennes, France), on the 19th of July last, at sunrise (the temperature being 10.5°, the height above sea level 1238 metres, sky cloudy, and haziness prevailing, with a westerly wind), he suddenly saw the whole sky, as it were, in a fiery glow, the sun orange-coloured, and, looking to the westward, he saw the image of the mountain he was ascending crowned with two rainbows, placed one above the other, and separated from each other by a greyish band, while the rainbows, instead of the seven, only exhibited two colours. The clouds, continuing to move, soon came near to the author, who then distinctly observed his own image. In fact, what he observed and describes is very akin to the well-known Broken spectrum of the Hartz Mountains, but with this distinction—that the phenomenon seen by the author of this brief notice has never been before noticed in the Cévennes.

Reagent for Detecting Ammonia in Lighting Gas.—V. Meunier.—The author prepares a sulphurico-alcoholic tincture of the fresh leaves of the *Colus Verschaffelti*, by infusing these leaves with absolute alcohol, to which a few drops of sulphuric acid are added. Strips of Swedish filtering-paper are dyed with this tincture, and, after having been dried in open air, are kept in well-stoppered bottles. When required for use, this paper is slightly moistened, and, being tinged green by alkalies, even if only mere traces thereof are present, is a valuable test for ascertaining, according to the author's experience, the presence of ammonia in gas, by only holding a strip of this paper for a moment in a current of illuminating gas.

Fertility of the Soil of Corsica.—J. Casanova.—The author states that, notwithstanding the long-continued and exceptionally-severe drought, and without having applied to his fields any other than a light dressing of stable manure, he has reaped 476 decalitres of wheat per hectare, the straw being, moreover, of exceedingly good quality, and exceeding 1.6 metres in height. This amounts to about 114.4 bushels (English measure) to rather more than 2 acres' surface. It should be observed that the Island of Corsica, as well as the adjacent Island of Sardinia (Italian territory), are both in a highly backward state as regards agriculture, and, moreover, only a very small area of these countries is under tillage.

Revue Hebdomadaire de Chimie, July 28, 1870.

Estimation of Glucose in Commercial Sugars.—J. Midy.—The author prepares a Fehling test-liquor of such a strength that 100 c.c. thereof are completely decomposed by 105 grms. of uncrystallisable sugar (1 c.c. of the liquor agrees, therefore, with 0.005 of glucose); a solution is also made of 20 grms. of the sugar to be tested in 150 c.c. of distilled water. To this solution, previously heated till near its boiling-point, is added, by means of a Mohr's burette (divided into 1.10th c.c.), $\frac{1}{2}$ c.c. of the Fehling cupreous liquor; the sugar solution is withdrawn from the source of heat, and, after having been stirred up, the suboxide of copper, if any has been formed, is allowed to settle. When this has taken place, a very small portion of the liquid is filtered through Swedish filtering paper, and to the filtrate is added a drop of a concentrated solution of ferrocyanide of potassium and acetic acid. If too much of the cupreous test-liquor has been added, the addition of the reagents alluded to will have the effect of causing the formation of the well-known precipitate of ferrocyanide of copper; and, in that case, a fresh sugar solution has to be made, and only $\frac{1}{4}$ c.c. of the cupreous test-liquor has to be added; and the ferrocyanide should not give indications of excess of copper in the filtered liquid as above alluded to. Such being the case, the operator knows that 20 grms. of sugar contain less than 0.0052, and more than 0.0026, of glucose; taking the average of these figures, which is 0.0039, and multiplying by 5, we learn that the sample of sugar tested contains about 0.0195 per cent. of glucose.

Plastic Material of Great Resistance Suitable for a Variety of Uses.—M. Rost.—The author mixes litharge and glycerine, in such proportions as may suit the purpose, so that it may form a creamy

liquid or a pasty mass. The mixture becomes, in a short time, a hard, homogeneous mass, which readily adheres to metals, resists the action of water and steam, and a temperature of 275°. In many instances, this paste is preferable and very superior to red-lead cement (linseed oil and red-lead); and this glycerine-litharge paste may be even used, when in very fluid state, for galvanoplastic copying, since the material preserves even fine engraved lines.

August 4th, 1870.

Naphthylamine Violet.—M. Scheurer.—This preparation, consisting of chlorhydrate of naphthylamine and chloride of copper, properly thickened, yields, at the ordinary temperature of the air, and after a few days of ageing, a dull, but pure violet; but, if the temperature of the ageing-room be about 30°, and much moisture present, the operation is finished within thirty-six hours, but the colour is bad and requires a clearing. The author, while experimenting found that, in order to obtain a good violet, the simultaneous action of hydrochloric and acetic acids are required, the latter producing, it appears, a peculiar, but not well explained, reaction.

Drying of Woollen Fabrics.—P. Havrez.—The author states that the complete drying of woollen fabrics is difficult, useless, and injurious to the fibre—difficult, because wool and woollen fabrics attract and retain readily up to 10 per cent. of moisture, which should be left in it; useless, because the wool cannot be carded unless moistened and oiled; and injurious, because too strongly-dried wool, as well as woollen fabrics (though in a less degree), become rough and lose suppleness. The author enters, at great length, into the various methods proposed for drying wool and woollen fabrics during the process of manufacture, and describes the stores and drying-rooms to be used.

Revue des Cours Scientifiques de la France et de l'Etranger,
August 6, 1870.

This number does not contain any papers relating to chemistry or sciences allied therewith, but contains an exhaustive and excellent lecture on—

Natural Selection and the Origin of Man—Dr. Claparede—And a lecture on the—

Mechanism of Flying of Birds and Insects.—Dr. Marey.—Illustrated by a series of woodcuts.

August 13, 1870.

This number does not contain any original papers relating to chemistry or sciences allied therewith, but it contains a most valuable paper on the—

Value of the Labours of Charles Darwin.—By no less an authority than the celebrated zoologist, M. Milne-Edwards. And also a paper on—

Commensalism in the Animal Kingdom.—M. van Beneden.—Wherein the author sets forth several interesting particulars about a very well-known animal—viz., sponge—which is a polyous animal reduced to its most simple form; while, chemically, it is a substance very akin to silk—that is to say, a nitrogenous, albuminous compound, almost identical with the fibrine which constitutes more than half the weight of raw silk.

NOTES AND QUERIES.

Analyses of Old Yellow Metal.—Will some of your kind correspondents favour me with the analysis of some samples of old yellow metal taken from ships (*Munts*), no matter by what maker, but stating, as near as possible, the period during which it had been on the ship, and to what ports the ship had been trading during that period. The information is wanted as accurate as possible, but especially the quantities of copper and spelter. If you will kindly oblige me with this information, through your columns, you will confer a great favour on a very old subscriber.—COPPER. PS. The metal must be thoroughly worn out.

TO CORRESPONDENTS.

* * The STUDENT'S NUMBER of the CHEMICAL NEWS will be published on Friday next, September 9th. Gentlemen holding official positions in the Universities, Medical Schools, &c., of the United Kingdom, where Chemistry and Physical Science form a part of the Education, who have not yet forwarded the necessary information to our office for publication in that number, will confer a favour by sending it with the least possible delay.

A. Halley.—Forwarded.

R. Galloway.—We are obliged for your kindness.

F. M. Rummington.—The article will be concluded as soon as possible.

Dr. J. Muter.—Received.

H. N. Draper.—Thanks for your communication; it arrived too late for this week.

THE CHEMICAL NEWS.

VOL. XXII. No. 563.

(STUDENTS' NUMBER.)

SCHOOLS OF CHEMISTRY.

EXAMINING BOARDS.

UNIVERSITY OF LONDON.

CANDIDATES for any Degree granted by this University are required to have passed the Matriculation Examination, to which no candidate is admitted unless he has produced a certificate showing that he has completed his sixteenth year.

The Fee for this Examination is £2.

The Examination will be held on Monday, January 4th, 1871, and includes the following subjects:—

NATURAL PHILOSOPHY.*

Mechanics.—

Composition and Resolution of Statical Forces.

Simple Machines (*Mechanical Powers*):—Ratio of the Power to the Weight in each.

Centre of Gravity.

General Laws of Motion, with the chief Experiments by which they may be illustrated.

Law of the Motion of Falling Bodies.

Hydrostatics, Hydraulics, and Pneumatics—

Pressure of Liquids and Gases, its equal diffusion, and variation with the depth.

Specific Gravity, and modes of determining it.

The Barometer, the Syphon, the Common Pump and Forcing-Pump, and the Air-Pump.

Acoustics—

Nature of Sound.

Mode and Rate of Propagation of Sound.

Musical Tones.

Optics—

Laws of Reflection and Refraction.

Formation of Images by Simple Lenses.

CHEMISTRY.

Heat—its sources. Expansion. Thermometers—relations between different Scales in common use. Difference between Temperature and Quantity of Heat. Specific and Latent Heat. Calorimeters. Liquefaction. Ebullition. Evaporation. Conduction. Convection. Radiation.

Chemistry of the Non-Metallic Elements; including their compounds as enumerated below—their chief physical and chemical characters—their preparation—and their characteristic tests.

Oxygen, Hydrogen, Carbon, Nitrogen. Chlorine, Bromine, Iodine, Fluorine. Sulphur, Phosphorus, Silicon.

Combining Proportions by weight and by volume. General Nature of Acids, Bases, and Salts. Symbols and Nomenclature.

The Atmosphere—its constitution; effects of Animal and Vegetable Life upon its composition.

Combustion. Structure and Properties of Flame. Nature and Composition of ordinary Fuel.

Water. Chemical peculiarities of Natural Waters, such as rain-water, river-water, spring-water, sea-water.

Carbonic Acid. Carbonic Oxide. Oxides and Acids of Nitrogen. Ammonia. Olefiant Gas, Marsh Gas, Sulphurous and Sulphuric Acids, Sulphuretted Hydrogen.

* The knowledge required of these subjects in Natural Philosophy is such as may be attained by attending a course of experimental lectures.

Hydrochloric Acid. Phosphoric Acid and Phosphuretted Hydrogen. Silica.

BACHELOR OF SCIENCE (B.Sc.).

This Degree is conferred on candidates who pass a satisfactory examination in Mathematics, Mechanical and Natural Philosophy, Botany, and Vegetable Physiology, Zoology, and Chemistry.

FIRST B.Sc. EXAMINATION.

No Candidate (with the exception of such as have obtained Honours at the Matriculation Examination in the preceding January) is admitted to this examination within one academical year of the time of his passing the Matriculation Examination.

The Fee for this Examination is £5.

The examination will commence on Monday, July 18th, 1871. It is conducted by means of printed papers; but the Examiners are not precluded from putting, for the purpose of ascertaining the competence of the Candidates to pass, *visà voce* questions to any Candidate in the subjects in which they are appointed to examine.

The First Examination includes the following subjects:—

NATURAL PHILOSOPHY.

Heat—

Sources of Heat; conduction—convection.

Effects of Heat; expansion generally—of water—of gases and vapours; liquefaction; vaporisation; latent heat; expansive force of steam; dew-point; gases and vapours compared.

Specific Heat.

Thermometers; Pyrometers.

Heat in the Radiant state.

Electricity—

Sources of Electricity.

Static Electricity; dual character—insulation—induction—specific inductive capacity—equivalent antithetic states—disruptive discharge—convection; Electroscopes—Leyden Jar, &c.

Dynamic Electricity; Conduction—the electric current—derived currents—induction of currents; Voltaic Pile and other voltaic arrangements.

Thermo-Electricity; Electro-Thermometer.

Magnetism—

Magnets, the Earth, &c.; Induction—communication—retention—Magnetic relations of iron, steel, &c.

Electro-Magnetism—as in the spark—in conducting media—in soft iron; Magneto-Electricity; principle of Electro-magnetic and Magneto-electric machines.

Terrestrial Magnetism.

INORGANIC CHEMISTRY.

Matter; simple and compound.

Elementary bodies classed. Metallic and Non-Metallic bodies.

Chemical Combination and Mechanical Mixture. Solution.

Outlines of Crystallography. Isomorphism. Dimorphism. Allotropic conditions of matter. Chemical Affinity. Laws of Combination by weight and by volume, as deduced from the history of the individual elements. Equivalent Numbers. Equivalent Volumes. Symbolical Notation, including questions on the Unitary System. Formulæ. Nomenclature.

Chemical actions produced under the influence of Heat. Nature of Combustion. Structure and Properties of Flame. Principles of Illumination. Chemical action of Light. Photography.

Oxygen. Ozone.

Hydrogen. Water.

Nitrogen. Chemical constitution of the Atmosphere. Diffusion of Gases. The Oxides of Nitrogen; Nitric Acid. Ammonia.

Chlorine, Bromine, and Iodine. Their compounds with Oxygen and Hydrogen. Theory of Bleaching.

Fluorine and Hydrofluoric Acid.

Sulphur. Sulphurous Acid. Manufacture and Chemical applications of Sulphuric Acid. Other Oxygen compounds of Sulphur. Sulphuretted Hydrogen.

Phosphorus. Oxygen and Hydrogen compounds of Phosphorus. Theory of Acids. Monobasic, Dibasic, and Tribasic Acids.

Carbon. Carbonic Oxide and Carbonic Acid. The principal Hydrogen compounds of Carbon. Manufacture of Coal Gas.

Silicon and Boron. Their compounds with the elements previously enumerated.

Metals. Characters of Metals as a class. Metallurgical Processes. Alloys. Classification of the Metals.

Potassium. Nitre. Gunpowder. Theory of the action of Gunpowder.

Sodium. Manufacture of Carbonate of Soda.

Barium. Strontium. Calcium. Mortars. Cements.

Magnesium. Aluminium. Glass. Porcelain.

Manganese. Iron. Composition and Properties of Cast-Iron. Wrought-Iron, and Steel. Chromium.

Cobalt. Nickel. Zinc. Cadmium.

Lead. Manufacture of White-Lead.

Copper. Mercury. Bismuth. Tin. Arsenic. Antimony.

Silver. Gold. Platinum.

Principal compounds of the Metals with the Non-Metallic Elements. Theory of Salts.

Principles of Mineral Analysis.

Principles of Electro-Chemistry.

For the First Examination, a knowledge of Inorganic Chemistry only is necessary.

EXAMINATION FOR HONOURS.

Candidates for Honours in Chemistry are examined in any of the following subjects, at the option of the Examiners:—

Elementary Substances and their combinations.

Electro-Chemistry.

Radiant Chemical Action.

In the Examination for Honours, the Candidate, being not more than twenty-two years of age, who most distinguishes himself in Chemistry and Natural Philosophy, will receive an Exhibition of Forty pounds per annum for the next two years.

SECOND B.Sc. EXAMINATION.

This Examination commences on Monday, October 24th. Candidates for this Examination who have not previously taken the Degree of B.A. is required either to have passed the First B.Sc. Examination at least one Academical year previously, or to have passed the First M.B. Examination, in this University.

The Fee for this Examination is £5.

This Examination embraces Organic Chemistry, including the following subjects:—

Ultimate analysis of Organic bodies. Calculation of Empirical Formulæ. Methods of controlling Empirical Formulæ. Determination of the Equivalents of organic acids and bases; examination of products of Decomposition; determination of the Vapour-density of volatile bodies.

Law of Substitution. Compound Radicals. Homologous Series.

The Chemical History of the Cyanogen group. Cyanogen. Hydrocyanic Acid. Cyanic Acid and Urea. Fulminates. Cyanuric Acid. Sulphocyanic Acid. Chlorides of Cyanogen. Uric Acid.

Amylaceous and Saccharine substances. Fermentation. Alcohol, Wine, Beer, Bread, &c.

Homologues of Alcohol. Ethers, simple and mixed. Oxidation of Alcohol. Aldehyd and Acetic Acid, and their homologues. Anhydrides, simple and mixed. Compound Ethers.

Diatomic Alcohols and their Acids. Glycol and Oxalic Acid and their homologues.

Triatomic Alcohols. Glycerine. Fatty and Oily bodies. Saponification.

Vegetable Acids;—the principal.

Ammonia and its derivatives. Ammonium and Ammoniacal Salts. Amides and Amines; their Classification. The chief natural Organic Bases.

Colouring Matters. Indigo and its derivatives. Principles of Dyeing.

The chief constituents of the Vegetable organism. Cellulose. Vegetable Fibrin. Albumen, Casein, Glutin, &c.

The chief constituents of the Animal organism. Animal Fibrin, Albumen, Casein, Gelatin. Blood, Milk, Bile, Urine, &c.

Decay, Putrefaction. Destructive Distillation.

The Chemical Principles of the process of Nutrition and of Respiration in Plants and Animals.

EXAMINATION FOR HONOURS.

The Candidate, not more than twenty-three years of age, who, in the Examination for Honours, most distinguishes himself in Chemistry, will receive Fifty pounds per annum for the next two years, with the title of University Scholar.

DOCTOR OF SCIENCE (D.Sc.).

This Examination is held within the first twenty-one days in June, and occupies four days.

No Candidate is admitted to the Examination for the Degree of D.Sc. until after the expiration of two Academical years from the time of his obtaining the Degree of B.Sc. in this University.

Candidates for the Degree of D.Sc. in any year, must give notice of their intention to the Registrar, and pay to him a Fee of Ten pounds, on or before the 1st of April.

Chemical Candidates can be examined either in Inorganic or Organic Chemistry; but no Candidate will be approved by the Examiners unless he has shown a thorough practical knowledge* of the *Principal Subject*, and a general acquaintance with the *Subsidiary Subject*, or *Subjects*, specified as belonging to the Branch so selected.

Inorganic Chemistry.

Principal Subject—Inorganic Chemistry.

Subsidiary Subjects—Either Organic Chemistry; or, Mineralogy, Crystallography, and Chemical Technology in its relations to Inorganic Chemistry.

Organic Chemistry.

Principal Subject—Organic Chemistry.

Subsidiary Subjects—Either Inorganic Chemistry; or, Chemical Technology, in its relations to Organic Chemistry, and the Chemistry of Animal and Vegetable Life.

EXAMINATIONS IN CONNECTION WITH THE DEPARTMENT OF SCIENCE AND ART, SOUTH KENSINGTON.

A sum of money is voted annually by Parliament for scientific instruction in the United Kingdom.

This sum is administered by the Science and Art Department.

The object of the grant is to promote instruction in Science, especially among the industrial classes, by affording a limited and partial aid or stimulus towards the founding and maintenance of Science schools and classes.

The following are among the Sciences towards instruction in which aid is given:—Acoustics, Light, Heat, Magnetism, and Electricity, Inorganic Chemistry, Organic Chemistry, Geology, Mineralogy, Mining, Metallurgy.

The assistance granted by the Science and Art Department is in the form of—1. Public Examinations, in which Queen's Medals and Queen's Prizes are awarded, held at all places complying with certain conditions. 2. Payments on results to teachers. 3. Scholarships and Exhibitions. 4. Building Grants. 5. Grants towards the purchase of apparatus, &c.

* It must be understood that the candidate for the Degree of D.Sc. is expected to be so fully conversant with the principal subject he may select, as to be able to go through any examinational test (whether theoretical or practical) of his acquirements in it that can be fairly applied.

CHEMICAL LECTURES AND LABORATORY INSTRUCTION.

UNIVERSITY COLLEGE.

FACULTY OF SCIENCE.

Dean.—Professor A. W. Williamson, Ph.D., F.R.S.

Vice-Dean.—Professor G. Croom Robertson, M.A.

Inaugural Lecture, on Tuesday, October 4th, at 3 p.m., by Professor Williamson.

The Session begins on Tuesday, the 4th of October, and ends on Friday, the 23rd of June.

It is divided into three terms, as follows: Michaelmas term, from October 4th until December 21st; Lent term, from January 3rd, 1871, till March 18th; Summer term, for Lectures, from March 20th till June 10th, all inclusive.

Chemistry.—Professor Williamson, Ph.D., F.R.S.

A. GENERAL COURSE.

Lectures daily, except Saturday, from 11 to 12 a.m.

Exercises on Tuesdays, Wednesdays, Thursdays, and Fridays, from 9 to 10 a.m.

Fee for the Whole Course of Lectures, £6 6s.; for a Half Course, £3 3s.; Perpetual, £9 9s.; for the Organic Course alone, £2 2s.

Fee for the Exercise-Class—For the Course, £2 2s.; for the Half Course, £1 1s.

The Instruction in this Class is of two kinds, consisting partly of Experimental Lectures by the Professor, partly of Exercises and personal instruction on the subject of the Lectures by Tutors, under the direction of the Professor.

The First Half of the Course to Christmas includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The Second Half of the Course, extending from January to March, includes the following subjects:—

I. Preparation and properties of the chief metals, including their characteristic reactions and most important salts. Detection of Metallic Poisons. Quantitative Estimation of Metals. Principles of Classification. Monatomic, Diatomic Metals, &c.

A weekly *viva voce* examination is held during the First Half Course and the commencement of the Second Half Course.

II. Organic Chemistry.

This commences in the second week in February, and occupies five lectures weekly till about the end of March. It includes a study of the characteristics and metamorphoses of the chief organic acids, bases, alcohols, ethers, colouring matters, &c. Methods of ultimate and proximate analysis. Determination of molecular weights. Theory of types; of compound radicals. Phenomena of fermentation, &c.

Practical Chemistry.

Mondays, Tuesdays, Thursdays, and Fridays, from 12 to 1.

The Course consists of about Forty Lessons, the first twenty being given in the five weeks preceding the Christmas Vacation, the remainder immediately after it.

The First Half includes the portion of Chemistry required for the Matriculation Examination.

For particulars, see the Prospectus of the Summer Session.

Fee for the Course, £4 4s.; Half Course, £2 12s. 6d.

B. ANALYTICAL AND PRACTICAL CHEMISTRY.

I. BIRKBECK LABORATORY.

The instruction in the Laboratory is intended for beginners as well as for more advanced students. It includes practice in the construction and use of apparatus for preparing the common gases, acids, bases, salts, &c., study of the qualitative methods of detecting and separating mineral or organic bodies from one another; also

quantitative analysis in the wet way, organic analyses, vapour-densities, &c.; instruction in gas analysis.

More advanced students are instructed in the methods of original research, especially in organic chemistry.

When accompanied or preceded by attendance on the Lectures on Chemistry, the Laboratory Course qualifies Students in the application of Chemistry to the Manufacturing Arts, Metallurgy, Medicine, or Agriculture, &c. Instruction is given in the principles and processes of Gas Analysis.

The Laboratory and Offices are fitted up completely with the most improved apparatus and utensils for experimental research, both for beginners, and for advanced Students. They are open daily, from 9 a.m. to 4 p.m., from the 4th of October until the end of July, with a short recess at Christmas and at Easter. Saturday, from 9 to 2.

Fees for the Session, 25 guineas; six months, 18 guineas; three months, 10 guineas; one month, 4 guineas; exclusive of the expense of materials. A deduction of about 40 per cent is made for Students who can attend only three fixed days per week.

A Gold Medal and Certificates of Honour are competed for by Students entered for the Session.

II. SUMMER COURSES.

I. Elementary Course.

About Forty Lessons, of one hour each, on Tuesday, Wednesday, Thursday, and Friday, from 11 to 12, commencing in the first week of May. Students are taught the construction and use of apparatus for the preparation of the most important gases, acids, &c. The characteristic tests for the presence of the common acids and bases, including the chief metallic and other poisons. Also the processes for separating these bodies from one another.

Solutions are frequently given in the class for investigation.

The first six weeks of the Course are occupied by the study of the chief non-metallic elements, and their simple compounds. Metallic salts, &c., are subsequently studied.

Fee for the Course, £4 4s., including cost of materials and apparatus.

II. Senior Course.

About Ten Lessons, of two hours each, on Mondays, from 10 to 12, commencing in the first week in May. The Course includes tests for fixed and volatile organic acids, nitrogenised acids, sugars, glycerine, &c.; organic bases and alkaloids, constituents of blood, milk, urine, &c.

Volumetric methods of quantitative analysis of acids, alkalies, urea, prussic acid, iron, &c., are practised.

Fee for the Course, £2 2s., including cost of materials and apparatus.

C. SUMMER MATRICULATION COURSE.

Professor Williamson, F.R.S., assisted by Mr. F. S. Barff, M.A., F.C.S.

This Course includes those parts of Chemistry which are required for the Matriculation Examination of the University of London.

The Course consists of about Twenty Lessons in Practical Chemistry, and of an equal number of Oral Lessons. The Practical Lessons include the preparation of the common gases and acids, &c., and the study of their characteristic properties in relation to the elementary laws of combination.

The other lessons are chiefly devoted to those parts of the subject which require fuller oral explanation than is given in the practical lessons. They include numerous exercises and questions, to which answers in writing are given by the Students. These Lessons will begin on Wednesday, April 5th, at 11 a.m.

The Class will meet on the first five week days, from 11 to 12; and some other Meetings will be announced when the Class has assembled.

Fee for the Class, £4 4s., including cost of materials and apparatus.

EVENING CLASSES.

The Session is divided into three Terms, each of ten complete weeks, exclusive of vacations—

I. The Michaelmas Term, beginning on Monday, the 10th of October, and ending on Thursday, December 15th.

II. The Lent Term, beginning on Monday the 9th of January, and ending on Thursday, March 16th.

III. The Summer Term, beginning on Monday, the 20th of March, and ending on Thursday, June 8th; the Easter Vacation extending from the 6th to the 17th of April, both days inclusive.

The object of these Classes is to extend the benefits of the College Tuition especially to gentlemen engaged elsewhere during the day, and to provide instruction in subjects not taught in the ordinary College Classes.

The Beadles have orders to admit gentlemen to any of the Classes, with the permission of the Professor or Teacher, as occasional visitors.

The Library is open for the convenience of the Students between 6.30 and 8.30 on the evenings when the Classes meet, except when it is wanted for other purposes.

Elementary Chemistry—Theoretical and Practical.

Professor Williamson, F.R.S., and Mr. Jones. Monday, from 7.30 to 9.30.

A Course of Twelve Lessons, of two hours each, in the Michaelmas and Lent Terms.

The elements of Chemistry are explained to the Class, and the experiments illustrating the subject are performed by the Students.

The subject will be the common Non-Metallic Elements and the common Metals, their Compounds and chief Properties, and the best methods of distinguishing and separating them.

All the experiments and analyses are repeated by each Student, or by not more than two Students jointly.

Fee, including the cost of materials, &c., £2 2s. per Term.

ROYAL SCHOOL OF MINES AND COLLEGE OF CHEMISTRY.

Professor of Chemistry.—Dr. E. Frankland, F.R.S.

The instruction in Chemical Science embraces:—

1. A course of Lectures on Experimental Chemistry, with special reference to the applications of Chemistry in the Arts and Manufactures.

2. A systematic Laboratory Course for the Practice of Chemical Analysis.

Chemical Lectures.—The Course consists of Forty Lectures on Mineral Chemistry and Thirty Lectures on Organic Chemistry.

The Lectures are delivered at the Royal College of Chemistry, Oxford Street.

Chemical Laboratory.—The general Laboratory for instruction in chemical manipulation, in qualitative and quantitative analysis, and in the method of performing chemical researches, is under the direction of Dr. Frankland, and will be opened on Monday the 3rd of October, 1870. The Royal College of Chemistry having become the property of the Government, its Laboratories are used for the instruction of the pupils of the Royal School of Mines.

There are three terms in the collegiate year, of three months each, commencing in the first week of October, January, and April respectively. The Laboratory hours are from 10 a.m. to 5 p.m., with the exception of Saturdays, when the Laboratory closes at 2 o'clock.

Each Laboratory Student works independently, there being no classes. All operations are superintended by the Professor and his assistants. A table with drawers, cupboards, and shelves, is appropriated to every pupil. The Institution supplies gas, fuel, and reagents. The larger and more expensive instruments of the Laboratory, such as air-pumps, thermometers, barometers, condensers, &c., may be used by the students, who are held responsible for their safety. The students have to pro-

vide themselves only with the apparatus specified in the Laboratory regulations. More advanced students engaged in private researches have to supply themselves with such materials as are not included amongst the ordinary reagents of the Laboratory.

Professor of Metallurgy.—Dr. Percy, F.R.S.

The course of instruction in Metallurgy consists of Lectures and Laboratory practice.

The object of the Lectures is the communication of such instruction as the student may be able to apply to the greatest practical advantage, when he may be subsequently engaged in conducting any metallurgical process.

Metallurgical Laboratory.—This Laboratory is conducted by Mr. R. Smith, under the direction of Dr. Percy, and is devoted to practical instruction in Metallurgy. It will be opened on the 3rd of October, 1870. The nature of this instruction will be adapted to the special requirements of the Students. It comprises:—Assaying in all its branches, especially of the more important metals, such as iron, copper, lead, tin, alloys of silver and gold, &c., and the examination of ores and metallurgical products.

The ability of the student to make trustworthy assays is in every case thoroughly tested; and no certificate of competency is given to a student who has not furnished satisfactory proof that he is able to obtain accurate results.

There are three terms in the collegiate year, of three months each. The Laboratory hours are from 10 to 4 during November, December, January, and February; and from 10 to 5 during the other months, with the exception of Saturdays, when the Laboratory is closed.

The charge for instruction in the Metallurgical Laboratory is £15 for three months; £12 for two months; and £7 for one month.

Evening Lectures.—This year these lectures will consist of two courses of eight lectures each. Subjects—Chemistry and Natural Philosophy.

KING'S COLLEGE.

*Professor of Chemistry.—W. A. Miller, M.D., V.P.R.S.**Professor of Practical Chemistry.—C. L. Bloxam.*

Students of the first and second years are admitted to the Course of Theoretical and Applied Chemistry. The Course commences with a view of the forces which concur to the production of Chemical Phenomena, after which the laws of Chemical Attraction are discussed, and the Non-metallic Elements and their principal compounds are described.

The metals and their principal compounds are next examined, care being taken to point out the applications of the Science to the Arts, and the processes of the different Manufactures of Metallurgy, and of Domestic Economy, are explained and illustrated.

Examinations of the Class, both *viva voce* and by written papers, are held at intervals during the course at the usual Lecture hour. Dr. Miller has published a work on Chemistry, which is used as a text-book by the class.

Third Year.—Students who have completed six Terms in this Department are admitted to a Course of "Practical Chemistry," consisting of Twelve Demonstrations in each term; and they go through a course of Manipulation in the most important operations of Chemistry, including the first steps of Analysis.

Any Student of this department may be admitted to this Class at any period of his study, on payment of an extra fee.

Experimental and Analytical Chemistry in the Laboratory.

—The object of this Class is to afford to Students who are desirous of acquiring a knowledge of analysis, or of prosecuting original research, an opportunity of doing so under the superintendence of the Professor and Demonstrator; Students may enter, upon payment of the extra fees, at any time except during the vacation, and for a period of one, three, six, or nine months, as may best suit their convenience. The laboratory hours are from ten till four daily, except Saturday, on which day the hours are from ten till one.

In addition to the Laboratory fee, each Student defrays the expenses of his own Experiments. The amount of this expense, which is comparatively trifling, is entirely under his own control.

Analytical and Experimental Chemistry.—Besides the Course of Chemical Lectures and the Summer Class of Practical Chemistry, provision is made for those Students who wish to become more minutely acquainted with the practical details of the Science. By means of this Class each Student is enabled to familiarise himself with the methods of analysis and research. After passing through a preliminary course of analytical operations, each Student devotes himself to such portions of the science as are most interesting to himself, or most likely to be practically useful to him. The Daniell Scholarship of £20, tenable for two years, is given every alternate year for original research in the Laboratory.

The Fees for admission to the Laboratory Class, exclusive of materials, are, for one month, £4 4s.; for three months, £10 10s.; for six months, £18 18s., &c.

EVENING CLASSES.

Classes for Evening Instruction are held at King's College from October to March, and during April, May, and June.

The Classes include one for the Elements of Chemistry and one for Practical Chemistry.

The fee for the former is £1 11s. 6d.; for the latter, £2 2s. The Classes meet twice a week.

PHARMACEUTICAL SOCIETY OF GREAT BRITAIN.

17, BLOOMSBURY SQUARE, W.C.

School of Pharmacy. The Session (1870-71) will commence on Monday, October 3rd, and extend to the end of July.

LECTURES ON CHEMISTRY AND PHARMACY, BY DR. REDWOOD.

These Lectures will be delivered on Monday, Tuesday, and Wednesday mornings, at 9 o'clock.

Part 1.—Physics in relation to Chemistry and Pharmacy.

" 2.—Chemistry of Inorganic Bodies.

" 3.—Chemistry of Organic Bodies.

Also Lectures on Botany and Materia Medica, by Professor Bentley. The first and second parts of this course, extending over the winter months, will be delivered at 17, Bloomsbury Square, on Friday and Saturday mornings, at 9 a.m. The third part of the course, on Systematic Botany, will be delivered at the Royal Botanic Gardens, Regent's Park, at 8 a.m.

Fees.—For registered apprentices and associates of the Society, for either of the above courses, £1 1s.; for either part separately, 10s. 6d. For those not connected with the Society, £2 2s. for either of the above courses; £1 1s. for either part separately. Students have free admission to the Library and Museum.

Laboratory.—The suite of Laboratories for Practical Instruction in General and Pharmaceutical Chemistry will be opened on Monday, the 3rd of October, under the direction of Professor Atfield, Ph.D. Fee for the entire session of ten months, Twenty-five Guineas. The Laboratories are open from 9.30 a.m. till 5 p.m. Students can enter at any period during the session.

Two Scholarships (the Jacob Bell Memorial Scholarship) of Thirty Pounds a year each, are open to competition annually in July.

The Board of Examiners meet monthly, and are required by the Pharmacy Act to examine "all candidates who may present themselves for examination in their knowledge of the Latin Language, in Botany, in Materia Medica, in Pharmaceutical and General Chemistry, and to grant Certificates of Competency."

LADIES' MEDICAL COLLEGE.

The Ladies' Medical College, established by the Female Medical Society in order to teach to educated

women the theory and practice of Midwifery and the accessory branches of medicine.

President—Lord Shaftesbury.

Hon. Sec.—Dr. James Edmunds.

The Seventh Annual Session will commence on Oct. 3, 1870, and extend to April, 1871, with a vacation of two weeks at Christmas.

The Lectures will occupy the afternoons of the Mondays, Tuesdays, Wednesdays, and Fridays, from 3 o'clock till 5.

Elementary Materia Medica.—(Teachship now vacant).

Elementary Chemistry.—Mr. J. R. Newlands.

Fee for two sessions' attendance upon the Lectures on Midwifery, Anatomy, and Physiology, Medical Science, and Hygiene, £10 10s.

Fee for each of the Extra Courses, one session, £1 1s.; two sessions, £1 11s. 6d.

Further details as to the objects and operations of the Society, and prospectuses of the College, may be obtained by letter to the Lady Secretary, 164, Great Portland Street, W.; or from the Hon. Sec., 4, Fitzroy Square, W.

CITY OF LONDON COLLEGE, LEADENHALL STREET, E.C.

The Annual Courses consist of three terms, each averaging ten experimental lectures: fee, 5s. per term. Subjects:—Junior Class, Chemistry—first year, Non-Metals; second year, Metals and (time permitting) Elements of Organic Chemistry. Senior class, 7 to 8 p.m., Practical Analysis.

BIRKBECK LITERARY AND SCIENTIFIC INSTITUTION.

EVENING CLASSES.

Chemistry.—Mr. G. Chaloner. Tuesday, 8 to 9.

NEW KENNINGTON INSTITUTE.

Evening Lectures and Practical Classes in Chemistry, Pharmacy, and all subjects connected with the Pharmaceutical Examinations, under the direction of Dr. Muter.

POLYTECHNIC INSTITUTION.

Course of Thirty Lessons in Inorganic Chemistry, under the superintendence of Professor Pepper. Tuesday, 8.30 to 10 p.m.

ROYAL VETERINARY COLLEGE, CAMDEN TOWN.

Chemical Professor.—Mr. R. V. Tuson.

LECTURES AT LONDON MEDICAL SCHOOLS.

ST. BARTHOLOMEW'S HOSPITAL & MEDICAL COLLEGE.

WINTER SESSION.

Lecturer.—Dr. Matthiessen, F.R.S. Monday, Wednesday, and Friday, at 9.15 a.m. One Course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. Matthiessen, F.R.S. One course, £2 2s.

CHARING CROSS HOSPITAL AND COLLEGE.

WINTER SESSION.

Lecturer.—Mr. C. W. Heaton, F.C.S. Monday, Thursday, and Friday, at 11. One session, £5 5s.

The Laboratory is open daily.

SUMMER SESSION.

Practical Chemistry.—Mr. Heaton, F.C.S. Monday and Friday. One session, £2 2s.

ST. GEORGE'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. H. M. Noad, F.R.S. Tuesday, Thursday, and Saturday, at 11.30. One course, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Dr. Noad, F.R.S. Monday, Wednesday, Thursday, Friday, at 10. One course, including the use of apparatus and materials, £4 4s.

GUY'S HOSPITAL.

WINTER SESSION.

Lecturers.—Dr. Debus, F.R.S., and Dr. Stevenson. Tuesday, Thursday, and Saturday, at 11. One course, £4 4s.

SUMMER SESSION.

Practical Chemistry.—Dr. Debus, F.R.S. Monday, Wednesday, and Friday, from 10 to 1. One course, £4 4.

LONDON HOSPITAL.

Lecturers on Chemistry.—Henry Letheby, M.B., and C. Meymott Tidy, M.B. Monday, Wednesday, and Friday, at 10.30 a.m.

Practical Chemistry.—Dr. Letheby, M.B. Monday, Tuesday, and Saturday, at 9 a.m.

ST. MARY'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. W. J. Russell, F.C.S. Monday, Tuesday, Thursday, and Friday, at 10.15. £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. W. J. Russell, F.C.S. Tuesday and Thursday, at 11.30 a.m.; and Saturday, at 9 a.m. One session, £3 3s.

MIDDLESEX HOSPITAL.

WINTER SESSION.

Lecturers.—Mr. Taylor and Mr. Heisch. Monday, Wednesday, Friday, and Saturday, at 11. One session, £6 6s.

SUMMER SESSION.

Practical Chemistry.—Mr. Taylor and Mr. Heisch, Monday, Wednesday, and Friday, at 11. One session, £3 3s.

ST. THOMAS'S HOSPITAL.

WINTER SESSION.

Lecturer.—Dr. A. J. Bernays. Wednesday, Thursday, and Friday, at 9. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Dr. A. J. Bernays. Tuesday and Thursday, 10 to 12; Friday, 11; Saturday, 10 to 1. One course, £3 3s.

WESTMINSTER HOSPITAL.

WINTER SESSION.

Lecturers.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 3 p.m.; Friday, at 3.30 p.m. One course, £5.

SUMMER SESSION.

Practical Chemistry.—Dr. A. Dupré, F.C.S. Tuesday and Thursday, at 10 a.m. One course, £2.

PRIVATE TEACHERS OF CHEMISTRY IN LONDON.

Mr. J. C. Braithwaite, 54, Kentish Town Road, N.W.—Chemistry and Toxicology, Monday and Thursday; Latin, Tuesday and Friday; Botany and Materia Medica, Wednesday and Saturday. All the classes commence at 8 p.m. Laboratory and Botanic Garden open daily, except Saturdays.

Mr. Henry Matthews, F.C.S.—Laboratory, 60, Gower Street, Bedford Square. Instruction in all branches of Practical Chemistry, particularly in its application to

Medicine, Agriculture, and Commerce. Laboratory open daily, except Saturday, from 10 to 5; on Saturday, from 10 to 1.

Dr. John Muter, M.A.—Laboratory, 289, Kennington Road. Prepares for examinations of Pharmaceutical Society.

Mr. John Newlands, F.C.S.—Laboratory, 13, Knowle Road, Brixton, S.W. Gives practical instruction in Analysis, and prepares gentlemen for various public examinations.

Mr. A. Vacher, 20, Great Marlborough Street, Regent Street.

UNIVERSITY OF OXFORD.

Professor of Chemistry.—Sir B. C. Brodie, Bart., M.A., F.R.S.

Demonstrator.—E. Madan, M.A.

A commodious Laboratory is attached to the New Museum.

Scholarships of about the value of £75 are obtainable at Christ Church, Magdalen, and other Colleges, by competitive examination in Natural Science.

UNIVERSITY OF CAMBRIDGE.

Professor of Chemistry.—G. D. Liveing, M.A.

MICHAELMAS TERM.

Practical Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 1 p.m.

LENT TERM.

Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, on the same days, at 1 p.m.

EASTER TERM.

Chemistry, by the Professor, on Mondays, Wednesdays, and Fridays, at 12.

Practical Chemistry, on the same days, at 1 p.m.

The Chemical Laboratory of the University is open daily, from 10 a.m. till 6 p.m.; so that Students can work there at such times as may be convenient to them; and the Professor will attend to give instruction at the times above specified.

PROVINCIAL SCHOOLS.

BIRMINGHAM.—MIDLAND INSTITUTE.

Lecturer on Chemistry.—Mr. C. J. Woodward, B.Sc. Tuesday and Thursday, at 8 p.m.

Practical Chemistry.—Mr. C. J. Woodward, B.Sc. Saturday, 3 to 6, and 6.30 to 9.30 p.m.

BIRMINGHAM.—QUEEN'S COLLEGE.

WINTER SESSION.

Professor of Chemistry.—Alfred Hill, M.D., Borough Analyst. Tuesday, Thursday, and Friday, at 12.

SUMMER SESSION.

Practical Chemistry.—Professor A. Anderson. Thursday and Friday, at 2 p.m.

BIRMINGHAM.—KING EDWARD VI. GRAMMAR SCHOOL.

Teacher of Chemistry.—G. Gore, F.R.S.

Assistant Teacher of Chemistry.—J. G. Grenfell, B.A.

BRISTOL.—BRISTOL MEDICAL SCHOOL.

WINTER SESSION.

Lecturer.—Mr. Thomas Coomber, F.C.S. Monday, Tuesday, Wednesday, and Thursday, at 8.15. One Course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—M. T. Coomber, F.C.S. Daily, except Saturday, at 8 a.m. One course, £3 3s.

ROYAL AGRICULTURAL COLLEGE,
CIRENCESTER.

Principal.—Rev. J. Constable, M.A.

Professors.

Agriculture.—J. Wrightson, F.C.S., M.R.Ag.Coll.

Chemistry.—A. H. Church, M.A.

Chemical Assistant.—E. Kinch.

Natural History.—W. R. McNab, M.D.

Veterinary Surgery.—J. McBride, M.R.C.V.S.

Surveying.—The Principal.

Drawing.—J. Miller.

Three courses of Lectures on Chemistry are being delivered during the present session, which commenced August 15th. Agricultural Chemistry, on Thursdays at 10.

Organic Chemistry, on Tuesdays and Wednesdays, at 9.

Inorganic Chemistry, on Mondays at 9, and Tuesdays at 2.

There are also three classes for the study of practical chemistry. Students occupy themselves with Chemical Manipulation during the first session, Qualitative Analysis during the second, and Quantitative Analysis during the third. The Laboratory of the College is open from 9 a.m. to 5 p.m. In the Private Laboratory of the Professor of Chemistry researches and analysis, relating chiefly to Agricultural Chemistry, are carried on.

Text Books.—Church's "Laboratory Guide" (2nd edition) "How Crops Grow" (Church and Dyer's edition), Fownes's "Chemistry," Anderson's "Agricultural Chemistry."

LIVERPOOL ROYAL INFIRMARY SCHOOL OF
MEDICINE.

WINTER SESSION.

Chemical Lecturer.—Mr. J. C. Brown, B.Sc., F.C.S.

Monday, Tuesday, Thursday, and Friday, at 10.15. One course, £5 5s.

SUMMER SESSION.

Practical Chemistry.—Mr. J. C. Brown, B.Sc., F.C.S. Tuesday, Wednesday, and Thursday, at 10.30. One course, £3 3s.

The Laboratory is open daily, from 10 to 4.

ANALYTICAL LABORATORY AND SCHOOL OF
TECHNICAL CHEMISTRY,

7, IRWELL CHAMBERS, FAZUCKERLY STREET, OLD HALL STREET, LIVERPOOL.

Conducted by Mr. A. Norman Tate.

Pupils may attend at any time between the hours of 9.30 a.m., and 5 p.m. (Saturdays, 9.30 a.m. and 1 p.m.), and may work every day, or any numbers of days, or portion of a day in the week, and for any period most convenient to themselves.

The Laboratory is also open two evenings per week for practical work.

Lectures one evening each week.

A separate working bench is provided for each Student, and he is also supplied with all ordinary chemicals, gas, fuel, and the more substantial portions of Laboratory apparatus, but must provide himself with test-tubes, beakers, and other apparatus of a fragile nature.

In addition to the ordinary chemical studies, the course of instruction will, as far as possible, comprise all such studies as may be required for the successful prosecution of the particular branch or branches of Applied Chemistry in which the pupil is to engage; as, for example, in the case of one intended for manufacturing pursuits, he would study architectural and mechanical drawing, so far as is required for the preparation of plans, &c., of chemical apparatus and manufactories, the nature and use of building materials, and the scientific principles and practical rules involved in building and constructive operations, and other scientific and practical information required in the arrangement, construction, and management of chemical manufactories, and the application of Chemistry to industrial pursuits.

COLLEGE OF CHEMISTRY, LIVERPOOL.

Principal.—Dr. Sheridan Muspratt, F.R.S.E., M.R.I.A., F.C.S., &c.

Assistant.—Mr. Martin Murphy, F.C.S.

The Course of Instruction in this College is entirely devoted to Laboratory work. The term is three months, and dates from time of entrance. Fee for working six days per week, £12 12s.; five days, £11 11s.; four days, £10 10s.; three days, £9 9s.; two days, £8 8s.; and one day per week, £6 6s. Hours of attendance, from 10 a.m. till 5 p.m. The Students' laboratories close at 1 p.m. on Saturdays.

Medical students may enter for one hour per day per session. Fee, £3 3s.

Certificates of attendance recognised by the University and Apothecaries' Hall of London, and Apothecaries' Hall of Ireland.

LEEDS SCHOOL OF MEDICINE.

WINTER SESSION.

Lecturer.—Mr. J. Chapman Wilson, F.C.S.

Daily, except Saturday, at 11 a.m. One course, £4 4s.

SUMMER SESSION.

Practical Chemistry.—Mr. Wilson, F.C.S.

Tuesdays and Thursdays, 11 to 12.30. One course, £2 2s.

LEEDS MECHANICS' INSTITUTION AND
LITERARY SOCIETY'S LABORATORY.

SESSION 1870-71.

Chemical Classes for Instruction in Elementary, Practical, and Analytical Chemistry.

Teacher.—Mr. George Ward, F.C.S.

The usual Sessional Course of Instruction in abstract and Applied Chemistry will commence on Thursday, September 22nd, at 8 p.m., on which evening the teacher of the classes will deliver an Introductory Lecture.

Fees, payable in advance:—Elementary Chemistry, Thursday, per session, £1 15s.; or 5s. 6d. per month. The subscription includes a selection of apparatus and material specially adapted for the course of instruction. To pupils providing their own materials, £1 1s. per session. Organic Chemistry, Friday, per session, 10s. 6d. Practical Chemistry, Tuesday, per session, £1 1s.; or 3s. 6d. per month, including apparatus and material. The session extends over seven months, from October to April inclusive.

HIGH HARROGATE COLLEGE, YORKSHIRE.

Professor of Chemistry.—Mr. W. G. Mason, F.C.S., Certificated Science Teacher.

MANCHESTER GRAMMAR SCHOOL.

DEPARTMENT OF MATHEMATICS AND PHYSICAL SCIENCE.

Masters.—T. S. Aldis, M.A. (Cantab.) W. M. Watts, D.Sc. (Lond.); J. Angell, Esq., and S. Edwards, B.A.

There is a large Chemical Laboratory attached to the School, and Chemistry and the various branches of Physics are regularly taught. Arrangements can be made for students to devote their whole time to Physical Science and Mathematics.

MANCHESTER ROYAL SCHOOL OF MEDICINE.

Lecturer on Chemistry.—Mr. Daniel Stone.

The usual course for the Medical Boards.

A Laboratory is connected with the school.

OWEN'S COLLEGE, MANCHESTER.

(IN CONNECTION WITH THE UNIVERSITY OF LONDON).

Chemistry.—Professor H. E. Roscoe, B.A., Ph.D., F.R.S., F.C.S.

Junior Class.—Wednesday and Saturday, from 9.15 to 10.15 a.m.

Subject: Inorganic Chemistry, comprising the laws of chemical combination, and a description of the properties

and mode of preparation of the non-metallic elementary bodies and their most important compounds.

Senior Class.—Tuesday and Thursday, from 9.15 to 10.15 a.m.

Subjects: Inorganic and Organic Chemistry, including the properties of the metals and their compounds, and the composition and relations of the best defined groups of organic bodies, and the laws regulating their formation.

Students are expected to answer the written exercises and attend the *viva voce* examinations given in these classes.

Fee, for each class, £3 3s. For both classes, £5 5s.

A *Recapitulatory Lecture*, without additional Fee, will be given on Friday at 9.15 a.m., which members of both classes will be required to attend.

Extra Class.—Wednesday, from four to five p.m.

Subject: Technological Chemistry.

The Chemical Principles involved in the most important Chemical Manufactures will be chiefly considered in this course.

Students attending this class must be acquainted with the principles of Chemical Science. Fee, £2 2s.

Analytical and Practical Chemistry.

LABORATORY COURSE.

Professor.—Henry E. Roscoe, B.A., Ph.D., F.R.S.

Senior Assistant.—Mr. C. Schorlemmer, F.C.S.

The aim of this course is to make the student practically acquainted with Chemical Science, to enable him to conduct analysis and original research, and to fit him for applying the science to the higher branches of Art, Manufactures, and Agriculture. To accomplish this, an attendance of not less than four days per week during three whole sessions is as a rule necessary. It is very advisable that each Laboratory Student should attend or should have attended the course of Lectures on Theoretical Chemistry.

The College Laboratory will be open for students daily from 10.30 a.m. until 5 p.m., except Saturdays, when it will be closed at 1.30. The Laboratory is closed from 1.15 until 2, for dinner.

The Laboratory is fitted with every convenience for the prosecution of practical chemistry, all branches of qualitative and quantitative analysis, and original research.

Each student is provided with a separate working table, set of tests, fuel, water, and gas, free of expense; but he is required to find his own apparatus, a few of the more expensive reagents, and the chemicals required for his experiments. Other apparatus or instruments of a more expensive description may be obtained on loan from the Laboratory Steward, subject to regulations to be prescribed by the Professor.

Fees for the Session.—Students working six days per week, £21; ditto, four days, £17 17s.; ditto, three days, £13 13s.; ditto, two days, £9 9s.; ditto, one day, £5 5s. Students entering the Laboratory Class at or after Christmas, for not less than two days per week, will be charged two-thirds of the fees for the whole session.

Special Fees for Shorter Periods.—For six months, six days per week, £17 17s.; five months, ditto, £15 15s.; four months, ditto, £13 13s.; three months, ditto, £10 10s.; two months, ditto, £7 7s.; one month, ditto, £4 4s.

Lectures on the methods of Qualitative and Quantitative Analysis, intended to supplement the instruction in Practical Chemistry, will be given by Mr. Schorlemmer, on Mondays, from 4 to 5 p.m.

First year's Laboratory Students are recommended to attend and answer the written exercises and the *viva voce* questions given in this class. Fee, £1 11s. 6d.

Chemical Calculations.—In this class, instruction and special practice is given, by Mr. Schorlemmer, on Wednesday, from 4 to 5 p.m., in the methods of Chemical Calculations, serving as supplementary to the Lecture and Laboratory Courses. Fee, £1 1s.

The Lectures on Chemistry in Owen's College are recognised by the University of London for its Medical

Degree, by the Royal College of Surgeons, and by the Apothecaries' Hall.

EVENING CLASSES.

Chemistry.

Professor H. E. Roscoe, B.A., Ph.D., F.R.S.

Lecture Class (First Course)—The Non-Metallic Elements.—Monday, from 8.35 to 9.35 p.m.

Lecture Class—(Second Course—The Metals). Friday, from 8.35 to 9.35 p.m.

Lecture Class (Third Course—Organic Chemistry).—Mr. C. Schorlemmer, F.C.S. Thursday from 8.35 to 9.35 p.m.

Laboratory Courses of Practical Chemistry.

Professor Roscoe, F.R.S., and Mr. Schorlemmer, F.C.S.

Junior and Senior Divisions.—Monday, from 6 to 8.30 p.m.

Pharmaceutical Course.—Monday and Wednesday.

COLLEGE OF MEDICINE, NEWCASTLE.

(IN CONNECTION WITH THE UNIVERSITY OF DURHAM).

Education in Pharmacy.—The Council of the College have added a Lectureship on Pharmacy to those at present existing. The proposed curriculum for Students in Pharmacy will consist of attendance on Lectures on Botany, Materia Medica, Chemistry, and Pharmacy. The Lectures on the two former of these subjects will be delivered in the summer, and those on the two latter in the winter session of study.

Lecturer on Chemistry.—Mr. A. Freire-Marreco.

Monday, Wednesday, Thursday, and Friday, at 4 p.m.

EVENING COURSES.

Chemical Physics.—Every Monday, at 7.30 p.m.

Inorganic Chemistry.—Every Wednesday, at 7.30 p.m.

Practical Pharmacy.—B. S. Proctor. Every Tuesday, at 7.30 p.m.

This course will include—General Processes and Physics applied to Pharmacy—Pharmacopœial Processes, and the most important recent improvements in Pharmaceutical preparations—Dispensing operations—Testing and the Test Solutions of the Pharmacopœia. The course will be illustrated, whenever practicable, with apparatus, experiments, and processes in operation.

Practice of Chemistry.—The Laboratories are open daily throughout the year from 10 to 5 o'clock. Non-Medical students can attend Laboratory practice and receive Instruction in Analysis.

Students attending the Laboratory practice and Lectures on Chemistry, who have passed the Durham Registration Examination, or any Examination in Arts recognised as its equivalent, will be registered on the books of the College as Students in Chemistry.

Fees.—Perpetual ticket for Pharmacy Curriculum, £6 6s. (this applies only to Students at present engaged in Pharmacy, and who enter before October, 1871). Separate Courses of Lectures (each), £4 4s. Laboratory Practice, 6 days per week, £31 10s. per annum; 4 days per week, £21 per annum. Special arrangements for shorter attendances. These fees admit to all the Courses in Chemistry.

SHEFFIELD.

Mr. W. Baker, F.C.S. Laboratory for Theoretical and Practical Chemistry, 46, High Street, Sheffield.

SCHOOL OF CHEMISTRY,

1, SURREY STREET, SHEFFIELD.

Mr. A. H. Allen, F.C.S., delivers a Course of Thirty Lectures on Inorganic Chemistry, in connection with the Science and Art Department.

Day and Evening Classes for Analytical Chemistry.

SHEFFIELD SCHOOL OF MEDICINE.

During the Winter Session, Mr. A. H. Allen, F.C.S., will deliver a Course of Forty-five Lectures on Chemistry.

SCOTLAND.

UNIVERSITY OF EDINBURGH.

Professor of Chemistry.—Dr. A. Crum Brown, F.R.S.

ROYAL COLLEGE OF PHYSICIANS AND
SURGEONS, EDINBURGH.

Lecturer on Chemistry.—Dr. Stevenson Macadam, F.R.S.E.

The Courses of Instruction in Chemistry include its applications to Medicine, Agriculture, and the Industrial Arts; and they qualify for the University of Edinburgh and other Universities, the Royal Colleges of Physicians and Surgeons, the Navy, Army, and Indian Medical Service, and the other Medical and Public Boards.

The Lectures on Chemistry commence on Wednesday, November 2nd, and continue to be delivered daily during the five months of the Winter Session. The Lectures form a complete Course; the New Nomenclature and Notation are employed throughout, and special Lectures in Technological Chemistry are given. Tutorial Class Examinations are held during the Session, and Excursions are arranged for visiting the principal Chemical Manufactories.

The Instructions in Analytical Chemistry are conducted in the laboratories at Surgeons' Hall, which are now open daily, under the personal superintendence of Dr. Macadam, for the instruction of gentlemen in Chemical Analysis, and the prosecution of researches in Manipulative Chemistry.

The Prelections in Practical Chemistry are also conducted in the Laboratories at Surgeons' Hall. The subjects selected for Examination are those with which Medical Students are specially called upon to exhibit a practical acquaintance.

Fees.—Lecture, £3 5s. (University Graduation, £4 4s.) Practical Chemistry (University, &c.), £3 3s.; Analytical Chemistry, £2 per month, £5 for three months, or £10 for six months.

UNIVERSITY OF GLASGOW.

Professor of Chemistry and Practical Chemistry.—Dr. Thomas Anderson, F.R.S.E.

ANDERSONIAN UNIVERSITY, GLASGOW.

Professor of Scientific Chemistry.—Dr. T. E. Thorpe.

GLASGOW MECHANICS' INSTITUTION.

Professor of Chemistry and Practical Chemistry.—Dr. R. Carter Moffat.

Assistants.—Mr. Marshall and Mr. D. Swan.

1. Course of Lectures on Chemistry for Medical Students, Manufacturers, Agriculturists, and others. Daily at 12; beginning October 26, and terminating in April.

The design of this Course, which comprises more than one hundred Lectures, is to instruct the Student in the Departments of Scientific Chemistry, and the application of its principles to Manufactures, Medicine, &c. Certificates of attendance on these Lectures are received by the Royal College of Physicians of London and Edinburgh, by the Royal Colleges of Surgeons of England, Ireland, and Edinburgh, by the Faculty of Physicians and Surgeons of Glasgow, by the Army, Navy, and East India Boards, and by the Apothecaries' Halls; they also qualify for graduation in the University of London, &c.

2. Instruction in the various Departments of Practical and Analytical Chemistry in the Laboratories, from 10 till 4.

3. Evening Course of Popular Lectures on General Chemistry, on Tuesdays at 8.30. Practical class in connection at 7.

4. Evening Classes for Technical Chemistry, on Monday, Wednesdays, and Fridays.

5. Practical Classes for Medical Students, daily in the Laboratory, at 10.

6. Summer Course of Practical Chemistry for Medical Students, commencing May 2, 1871, at 11.

GLASGOW VETERINARY COLLEGE.

Professor of Chemistry.—Dr. R. Carter Moffat.

IRELAND.

DUBLIN.—TRINITY COLLEGE,

Professor of Chemistry.—Dr. Apjohn, F.C.S.

ROYAL COLLEGE OF SURGEONS, DUBLIN.

Professor of Chemistry.—Dr. Barker.

QUEEN'S COLLEGE BELFAST.

Professor of Chemistry.—Dr. Andrews, F.R.S., &c.

QUEEN'S COLLEGE, CORK.

Professor of Chemistry.—Dr. Blyth.

QUEEN'S COLLEGE, GALWAY.

Professor of Chemistry.—Dr. T. H. Rowney.

A Laboratory for Practical Instruction is attached to all the Queen's Colleges. The usual Practical Course for the Medical Boards is given in the summer.

ROYAL COLLEGE OF SCIENCE FOR IRELAND,
STEPHEN'S GREEN, DUBLIN.

This College supplies, as far as practicable, a complete course of Instruction in Science, applicable to the Industrial Arts. The Subjects of Instruction are:—Pure and Applied Mathematics, Descriptive Geometry, and Mechanical Drawing, Mechanism, Theoretical and Applied Chemistry, Chemical Analysis, Physics, Botany, Zoology, Geology, and Palæontology, Mineralogy, Mining, Machinery, Surveying, and Agriculture.

Professor of Theoretical Chemistry.—W. K. Sullivan, Ph.D., V.P.R.I.

Professor of Analytical and Applied Chemistry.—R. Galloway, F.C.S.

Assistant Chemist.—W. Plunkett, F.C.S.

A Course of Lectures on Inorganic and Organic Chemistry is delivered by Dr. Sullivan three times a week during the session. Fee for the entire course, £2.

A Course of Lectures on Technological Chemistry is delivered by Mr. Galloway twice a week during the session. Fee for the course, £2.

The Chemical and Metallurgical Laboratories, under the Direction of Mr. Galloway, are open every week day during the session, except Saturday. Instruction is given in the different branches of Analytical Chemistry, including Assaying, and in the methods for performing Chemical research. Each student is taught, not in class, but separately and independently; and he is supplied with a separate working table, with reagents, fuel, water, gas, and the larger and more expensive apparatus. Fee, for the session of nine months, £12; or for three months, £5; or for one month, £2.

There are four Royal Scholarships, of the value of £50 each, yearly, with free Education, including Laboratory Instruction, tenable for two years; two become vacant each year; they are given to students who have been a year in the College. There are also nine Exhibitions attached to the College, of the yearly value of £50 each, with free Education, including Laboratory Instruction, tenable for three years; three become vacant each year. These are awarded at the annual May Examinations of the Science and Art Department.

A Diploma of Associate of the College is granted at the end of the three years' Course.

The Session commences on Monday, October 3rd.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the *CHEMICAL NEWS*, with their copious indices, will, therefore, be equivalent to an English edition of the "*Jahresberichte*."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, August 29, 1870.

This number contains nothing but a memoir strictly relating to geometry. The meeting of the Academy only lasted for a quarter of an hour.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 12, 1870.

This number contains the following original essays and papers:—

Observations on some of the Compounds of Cerium.—F. L. Sonnenschein.—After a brief review of the labours of others on this subject, the chief point of interest in this paper is the author's communication of the fact that oxide of cerium is an excellent reagent and test for strychnia. When the last-named substance is well moistened with concentrated sulphuric acid, and there is added to it a mixture of proto-sesquioxide of cerium, a very fine blue colouration ensues, which gradually verges to cherry-red, and then remains unchanged, even for several days. The author states that, by this test, even so small a quantity of strychnia as 0.00001 grm. can be detected. Other alkaloids yield, with the same test, quite different reactions, as, for instance—brucine, orange, becoming at last yellow; morphine, olive-brown, finally brown; narcotine, first brownish, cherry-red, remaining at last cherry-red; quinine, pale yellow; cinchonine remains colourless.

On Anthrachinon.—G. Græbe and C. Liebermann.—This memoir treats chiefly on the action of caustic potassa at a high temperature upon anthrachinon, and on the yellow substance, red-coloured in alkaline solution, which is the result of that reaction. The authors state that the yellow colour of the body alluded to is due to the presence of anthrachinhydron, while the anthrachydrochinon is itself a colourless substance.

Alizarine and Purpurine.—G. Græbe and C. Liebermann.—They have found that the anthrachinon-bisulpho acid can be obtained directly from anthracen, by the action of a mixture of fuming and ordinary concentrated sulphuric acid upon the bibromide or bichloride of anthracen. This reaction takes place according to the following formula:—

The sulpho acids so obtained yield, when fused with caustic potassa, alizarine. The authors describe, further, a series of experiments made with the view to convert alizarine into purpurine, but they did not obtain the last-named substance.

Wax Contained in Opium.—O. Hesse.—The author describes, at great length, the process by which, from the so-called *feces opii*, may be obtained a waxy matter which, on closer investigation, proved to consist of two different substances—viz., cerotate of ceryl and palmitate of ceryl—the latter forming the chief portion of the mass. The first-named substance fuses at 82.5°, the last-named substance, $C_{48}H_{90}O_2$, fuses at 79°, is soluble in alcohol, chloroform, ether, and acetone, and crystallises in prismatic-shaped crystals.

Contribution to our Knowledge on Diamylen.—W. von Schneider.—This paper is chiefly a series of very lengthy and complicated formulae.

Bromogallic Acid.—E. Prioznik.—This paper is divided into the following sections:—Bromogallic acid and acetyl-chloride; tetracetyl-gallic acid and bromine; gallic acid and bromated bromide of acetyl; bibromogallic acid and oxide of silver; bibromogallic acid and aniline; bibromogallic acid and cyanides.

New Method of Formation of Chinons.—P. Weselsky.

Contribution to our Knowledge on Stanno-Triethyl.—A. Ladenburg.

Nitro-Derivatives of the Phenyl-Acetic Acid.—B. Radziszewski.—The author describes ortho-nitro-phenyl-acetic acid, a solid substance, soluble in water, fusing at 98°, and crystalline; its salts crystallise with difficulty.

Carbanilidic Acid Ether.—H. Schiff.—This memoir is divided into the following sections:—Triphenyl-cyanurate (*cyanurat*); triphenyl-isocyanurate—

diphenyl-carbamide; triphenyl-biuret.

Aromatic Cyanates.—A. W. Hofmann.—This lengthy memoir is divided into the following sections:—Phenyl-urethan; phenyl-cyanate;

tolyl-urethan; tolyl-cyanate; xylyl-urethan; xylyl-cyanate; naphthyl-urethan; naphthyl-cyanate.

The following are lecture experiments, communicated by Dr. A. W. Hofmann:—

Ignition of Hydrogen Compounds in Contact with Fuming Nitric Acid.—When a few drops of rather warm fuming nitric acid are poured into a glass cylinder containing the non-spontaneous combustible phosphuretted hydrogen gas, a very violent, and even somewhat dangerous detonation ensues. Pure sulphuretted hydrogen, best obtained free from excess of hydrogen, by evolving it from native black sulphuret of antimony and hydrochloric acid gas, becomes immediately ignited when brought into contact with some strong fuming nitric acid. When a few c.c. of moderately-warmed and strong nitric acid are poured into a moderately large-sized cylinder, containing hydriodic acid gas, a red flame bursts forth, violet-coloured fumes are given off, and the interior of the cylinder becomes covered with steel-grey crystals of iodine.

Colouring Power of Some of the Aniline Dyes.—After referring to the great many experimental illustrations of the divisibility of matter, the author quotes the following:—The solution of any salt of rosaniline (for this purpose, since only very dilute solutions are used, it is quite indifferent what salt be used), mixed with a few drops of acetic acid, and so diluted with water as to have x part of the rosaniline salt to 1,000,000 of water (1 milligram. to 1 litre of liquid) is yet deeply carmine-coloured, and yields a fluid capable of dyeing silk thread, previously moistened with dilute acetic acid. When the coloured liquid is diluted with water, so that 25,000,000 parts of that liquid are present (1-25th of a milligram. of the salt to the litre), the liquid is yet distinctly coloured; and silk, immersed in this bath for a quarter of an hour, is dyed pale red-coloured when removed from the liquid. Even x part of the rosaniline salt in 100,000,000 parts of water is visible, if the layer of liquid seen through is about $\frac{1}{4}$ metre thick.

Formation of Nitric Acid during the Combustion of Hydrogen in Air.—The author describes an experiment, intended to prove, on a large scale, the formation of water during the combustion of hydrogen, so that 30 grms. of water were formed in as many minutes. The water thus formed reddened tincture of litmus, had a decidedly acid taste, and yielded all the characteristic tests of nitric acid.

Fluid Cyanogen.—A full translation appeared in our last number.

Alternate Reduction and Oxidation.—A well-polished small copper bell is placed in a ring on a triangle, and made red-hot by passing a strong gas flame to play upon it, so as to render the metal red-hot, and, consequently, very soon black. As soon as this is the case, a strong current of hydrogen gas is directed upon the metal, by means of a flexible tube fastened to the neck of a glass funnel large enough to cover the bell. As soon as the hydrogen gas comes into contact with the red-hot metal, the layer of black oxide of copper is removed, and the metal appears as before it was heated. By removing the current of hydrogen, the oxygen of the air again acts upon the hot metal; and thus this alternate oxidation and reduction may be continued, provided the metal had been made thoroughly red-hot to begin with. The hydrogen should be pure, and free from traces, even, of sulphur or arsenic, in order that the experiment be successful.

Size of the Gas Molecules of Inorganic Compounds.—R. Rieth.

Some of the Derivatives of Muconic Acid.—H. Limpricht.—This paper contains brief notices of the following bodies:—Bromo-muconic acid; tribrom-adipic acid; tetrabrom-adipic acid; oxy-muconic acid; adipino-tartaric acid; trioxo-adipic acid.

Preliminary Notice on Alizarine.—V. Wartha.—The author states that, being engaged with researches on Turkey-red dyeing, he has found that the peculiarly-brilliant red colour known by this term is due to a peculiar combination of alizarine with a fatty acid, which compound is soluble in a mixture of ligroine and ether, and does not even adhere very strongly to the cloth, since it may be readily removed therefrom by the liquid mixture alluded to. On evaporating this solution, there is left a brilliantly scarlet-coloured fatty substance, which, only after having been fused with caustic potassa, exhibits the characteristic reactions of alizarine. The author also states that the preparation of alizarine from madder is readily performed by first exhausting the substance (madder) with ligroine, and next treating it with a mixture of alcohol and hydrochloric acid (alcohol saturated with the gas). On diluting this solution with much water, the alizarine is precipitated, in almost a chemically pure state, in the shape of an orange-coloured flocculent body. A carefully-conducted comparative investigation has proved to the author that the vegetable alizarine sublimes at between 130° and 140°. The synthetically-prepared artificial alizarine requires a temperature of from 280° to 300°. By ligroine, the author means light petroleum oil, such as is used in vapour or sponge lamps.

Preparation of Naphthylamine.—M. Ballo.

Dyes and Pigments to be Derived or Obtained from the Salts of Rosaniline, Brom-Naphthaline, and Naphthylamine.—M. Ballo.—These memoirs are too lengthy to admit of any useful abstraction.

Revue des Cours Scientifiques de la France et de l'Etranger, August 20 and 27, and September 3, 1870.

This number does not contain any original papers relating to chemistry and collateral sciences, but the lectures on—

Flying of Birds.—M. Marey.—Are published in full, illustrated by several diagrams and woodcuts.

Royal School of Mines.—Director, Sir Roderick Impey Murchison, Bart., K.C.B., F.R.S., &c.

During the Twentieth Session, 1870-1871, which will commence on the 10th of October, the following COURSES of LECTURES and PRACTICAL DEMONSTRATIONS will be given:—

1. Chemistry.—By E. Frankland, Ph.D., F.R.S.
2. Metallurgy.—By John Percy, M.D., F.R.S.
3. Natural History.—By T. H. Huxley, LL.D., F.R.S.
4. Mineralogy } —By Warrington W. Smyth, M.A., F.R.S.
5. Mining }
6. Geology.—By A. C. Ramsay, LL.D., F.R.S.
7. Applied Mechanics.—By T. M. Goodeve, M.A.
8. Physics.—By Frederick Guthrie, B.A., Ph.D.

Instruction in Mechanical Drawing, by the Rev. J. Haythorne Edgar, M.A.

The Fee for Students desirous of becoming Associates is £30 in one sum, on entrance, or two annual payments of £20, exclusive of the Laboratories.

Pupils are received in the Royal College of Chemistry (the Laboratory of the School), under the direction of Dr. Frankland, and in the Metallurgical Laboratory, under the direction of Dr. Percy.

Tickets to separate Courses of Lectures are issued at £3 and £4 each.

Officers in the Queen's Service, Her Majesty's Consuls, Aiding Mining Agents and Managers may obtain tickets at reduced prices.

Certificated Schoolmasters, Pupil-Teachers, and others engaged in education, are also admitted to the Lectures at reduced fees.

His Royal Highness the Prince of Wales grants two Scholarships, and several others have also been established by Government.

For a Prospectus, and information, apply to the Registrar, Royal School of Mines, Jermyn Street, London, S.W.

TRENHAM REEKS, Registrar.

Pharmaceutical Society of Great Britain,

17, Bloomsbury Square, W.C.—School of Pharmacy—Session 1870-71. The Session will commence on Monday, October 3rd, and extend to the end of July.

LECTURES ON CHEMISTRY AND PHARMACY, BY PROFESSOR REDWOOD. These Lectures will be delivered on Monday, Tuesday, and Wednesday mornings, at 9 o'clock.

- Part 1.—Physics in Relation to Chemistry and Pharmacy.
- " 2.—Chemistry of Inorganic Bodies.
- " 3.—Chemistry of Organic Bodies.

ON BOTANY AND MATERIA MEDICA, BY PROFESSOR BENTLEY.

- Part 1.—Structural and Physiological Botany.
- " 2.—Organic Materia Medica.
- " 3.—Systematic Botany and Practical Demonstrations of Plants.

The first and second parts of this Course, extending over the Winter months, will be delivered at 17, Bloomsbury Square, on Friday and Saturday mornings, at 9 o'clock. The third part of the Course, on Systematic Botany, will be delivered at the Royal Botanic Gardens, Regent's Park.

FEES.—For Registered Apprentices and Associates of the Society, for either of the above Courses, One Guinea; for either part separately, Half a Guinea. For those not connected with the Society, Two Guineas for either of the above Courses; One Guinea for either part separately.

Students have free admission to the Library and Museum. LABORATORY.—The Suite of Laboratories for Practical Instruction in General and Pharmaceutical Chemistry will be opened on Monday, October 3rd, under the direction of Professor Atfield. Fee for the entire Session of ten months, Twenty-five Guineas. The Laboratories are open from half-past 9 a.m. till 5 p.m. Students can enter at any period during the Session.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

South London School of Chemistry and Pharmacy,

New Kennington Institute, 289, Kennington Road, S.E. Director, and Teacher of Chemistry, Dr. J. Muter, M.A.

Botany and Materia Medica.—Dr. Renadin.

Practical Chemistry.—Mr. Earp.

Evening Classes for gentlemen engaged in business in Latin, Mathematics, Chemistry, Botany, Materia Medica, Physics, and Natural History. Special preparation for the Examinations at the London University and Pharmaceutical Society.

For terms and particulars, apply to Dr. Muter, or to Mr. W. Baxter, Secretary.

*. A Vacancy in the Laboratory for a Pupil-Assistant.

North London School of Chemistry, Pharmacy, &c.—

For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has had laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870-1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

The LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

Royal Veterinary College, Great College Street, Camden Town, London.

The Lectures will commence at the above Institution on Tuesday, October 4th.

The Introductory Address will be delivered by Professor Tuson, at 12 o'clock.

Anatomy, Physiology, and Pathology of the Horse.—Professor Spooner. Anatomy, Physiology, and Pathology of other Domesticated Animals.—Professor Simonds.

Descriptive Anatomy, with Physiology.—Deputy Professor Pritchard. Chemistry, Materia Medica, and Toxicology.—Professor Tuson. Anatomical Demonstrations.—Assistant Professor Axe.

Infirmary Practice and Clinical Instruction daily.—Professors Spooner, Simonds, and Pritchard.

Perpetual fee to all the Lectures, with Infirmary Practice and Anatomical Demonstrations daily, 25 guineas.

It is desirable that intending Pupils should present themselves at the Royal Veterinary College, for matriculation at 10 o'clock a.m. precisely, on Thursday, the 29th of September next.

A Prospectus will be forwarded on application.

CHARLES SPOONER, Principal.

August 25, 1870.

King's College.—Medical Department.—The

WINTER SESSION will open on Monday, October 3, with an Introductory Lecture by Professor Wood, at 3 p.m.

Warneford Scholarships.—Students entering the Medical Department of this College in October, 1870, will have the exclusive privilege of contending for two Scholarships of £25 each, for three years. These Scholarships are given for proficiency in Divinity, Classics, Mathematics, History, and English.

Five Medical Scholarships are awarded at the close of each Winter Session for proficiency in professional subjects, viz., one of £40 for two years, one of £30 for one year, and three of £20 for one year.

Endowed Prizes of the value of £25, £15, £10, and £4 4s. each, and College Prizes of the value of £50, are annually awarded.

For further information apply personally, or by letter marked outside "Prospectus," to J. W. Cunningham, Esq., Secretary.

Methylated Spirits.—David Smith Kidd,

Licensed Maker, Commercial Street, Shoreditch, N.E. Also FINISH, FUSEL OIL, and RECT. NAPHTHA.

Water-glass, or Soluble Silicates of Soda

and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Chloride of Calcium (Purified Muriate of Lime),

total insoluble impurities under ¼ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under ¼ per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCASHIRE.

**ANALYTICAL LABORATORY AND SCHOOL OF
TECHNICAL CHEMISTRY.**

7, IRWELL CHAMBERS, OLDHALL STREET, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting
Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactories, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

College of Chemistry, Duke Street, Liverpool.

(Established 1848.) *Founder and Principal*, Dr. Sheridan Muspratt, M.D., Hon., &c., &c.; Author of "Chemistry as Applied to the Arts, Manufactures," &c., "Dr. Muspratt's Plattner on the Blowpipe," &c., &c. *Director of Studies, and Analyst*, Martin Murphy F.C.S., &c.

The system adopted is one wholly devoted to a course of Practical Work and Demonstration of the Principles of Chemical Science in its various sections and relations.

The Fee for the Course (twelve months) is Forty Guineas; or, per Session of three months, Twelve Guineas, payable in advance.

The Course and Session may commence at any current date. Students are received for limited periods at special fees. Students provide their own Apparatus, and such reagents of the precious metals as they may want.

Assays and Analyses of every description conducted. Fees moderate.

Chemical Manufacturing Processes and Works investigated, inspected, and supervised.

Full Prospectus on application.

The Certificates of Attendance are acknowledged by the University and Apothecaries' Hall of London, and the Apothecaries' Hall of Ireland, &c.

TECHNICAL EDUCATION.**SCIENCE AND ART DEPARTMENT.****Royal College of Science for Ireland,**
Stephen's Green, Dublin.

SESSION 1870-71.

This College supplies, as far as practicable, a complete Course of Instruction in Science applicable to the Industrial Arts, especially those which may be classed broadly under the heads of CHEMICAL MANUFACTURES, MINING, ENGINEERING, and AGRICULTURE.

A Diploma of Associate of the College is granted at the end of the Three Years' Course.

The Course of Instruction is recognised by the Secretary of State for India as Qualifying for Appointments in the Engineering Department.

There are Four Royal Scholarships, of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years; two become vacant each year. They are given to Students who have been a year in the College. There are also Nine Exhibitions attached to the College, of the yearly value of £50 each, with Free Education and Laboratory Instruction, tenable for three years; three become vacant each year. These are awarded at the Annual May Examinations of the Science and Art Department.

The Fees are £2 for each Course, or £10 for all the Courses of each year, with the exception of Laboratory, the Fee for which is £12 for the full course of Nine months, or £2 per month.

SUBJECTS OF INSTRUCTION.

Applied Mathematics, Mechanism and Machinery, Descriptive Geometry, Geometrical, Mechanical, and Engineering Drawing, Experimental Physics, Chemistry (Theoretical and Practical), Botany, Zoology, Geology and Palaeontology, Mining, Surveying, Agriculture.

The Laboratory is open for Instruction in Practical Chemistry, Metallurgy, and Assaying, from 10 to 4 o'clock every week day during the Session, except Saturdays and holidays.

The Session commences on Monday, October 3rd.

Programmes may be obtained on application to the Secretary, Royal College of Science, Stephen's Green, Dublin.

FREDERICK J. SIDNEY, LL.D., Secretary.

**Manchester Grammar School. Department
of MATHEMATICS and PHYSICAL SCIENCE.****PROFESSORS:**

Mathematics—T. S. Aldis, M.A.
Chemistry—W. Marshall Watts, D.Sc.
Physics—J. Angell.

Arrangements can be made for Students to devote their whole time to Chemistry.

MICHAELMAS TERM commences on Tuesday, September 20th.

EVENING CLASSES.

Inorganic Chemistry—Lecture Class, Thursday, from 7.30 to 8.30. Fee, 15s.

Practical Chemistry—Monday, from 7 to 9. Fee, £3 3s.

The School is in connection with the Department of Science and Art; and Examinations are held at the School in May. Two hundred and fifty-six pupils passed the last Examination.

University of Aberdeen.—Chancellor, His

Grace the Duke of Richmond. *Vice-Chancellor and Principal*, the Very Rev. P. C. Campbell, D.D. *Lord Rector*, M. E. Grant Duff, M.A., M.P.

FACULTY OF MEDICINE—SESSION 1870-71.

WINTER SESSION, commencing on Wednesday, October 26th.

Anatomy—Professor Struthers, M.D. 11 a.m. £3 3s.

Practical Anatomy and Demonstrations—Professor Struthers and the

Demonstrator. 9 to 4, and 9 a.m. £2 2s.

Chemistry—Professor Brazier. 3 p.m. £3 3s.

Institutes of Medicine—Professor Ogilvie, M.D. 4 p.m. £3 3s.

Surgery—Professor Pirrie, C.M., F.R.S.E. 10 a.m. £3 3s.

Practice of Medicine—Professor Macrobain, M.D. 3 p.m. £3 3s.

Midwifery and Diseases of Women and Children—Professor Inglis,

M.D. 2 p.m. £3 3s.

Zoology, with Comparative Anatomy—Professor Nicol, F.G.S. 2 p.m.

£3 3s.

Medical Logic and Medical Jurisprudence—Professor Ogston, M.D.

9 a.m. £3 3s.

SUMMER SESSION, commencing on the First Monday of May.

Botany—Professor Dickie, M.D. 9 a.m. £3 3s.

Materia Medica (100 Lectures)—Professor Harvey, M.D. 3 and 4 p.m.

£3 3s.

Practical Anatomy, and Demonstrations—Professor Struthers and the

Demonstrator. 9 to 4, and 2 p.m. £2 2s.

Practical Chemistry—Professor Brazier. 10 a.m. £3 3s.

Zoology, with Comparative Anatomy—Professor Nicol. 11 a.m.

£3 3s.

The Anatomical Course in Summer includes Instruction in General

Anatomy and in the Use of the Microscope; and Instruction in Osteo-

logy for Beginners.

Matriculation Fee (including all dues) for the Winter and Summer

Sessions, £1. For the Summer Session alone, 10s.

Royal Infirmary: Daily at Noon. Physicians—Drs. Harvey, Smith,

and Beveridge. Surgeons—Drs. Pirrie, Kerr, and Fiddes. Junior

Surgeon—Dr. A. Ogston. Ophthalmic Surgeon—(Vacant). Dental

Surgeon—Mr. Williamson. Pathologist—Dr. Rodger. Perpetual

Fee to Hospital Practice, £6—or, first year, £3 10s.; second year, £3.

Clinical Medicine—Drs. Harvey and Smith. £3 3s.

Clinical Surgery—Drs. Pirrie, Kerr, and Fiddes. £3 3s.

Pathological Anatomy—Dr. Rodger. £2 2s.

A three month's course of Practical Ophthalmology is given in Sum-

mer by Dr. A. Ogston, commencing early in May.

General Dispensary and Lying-in and Vaccine Institution: Daily.

Eye Institution—Daily.

Practical Midwifery—Under the Superintendence of Dr. Inglis.

Royal Lunatic Asylum: Physician—Dr. Jameson. Clinical Instruc-

tion is given for three months in the year.

The Regulations relative to the Registration of Students of Medi-

cine, and the Granting of Degrees in Medicine and Surgery, may be

had of Dr. Macrobain, Dean of the Faculty of Medicine.

Full information regarding the Classes and Degrees in the Facul-

ties of Arts, Law, and Divinity, and in regard to Bursaries and

Scholarships, will be found in the UNIVERSITY CALENDAR,

published by Messrs. Wylie and Son, Union Street, Aberdeen—by

post, 2s. 2d.

Lectures on Mineralogy applied to Geology

and the Arts are given by Professor TENNANT, F.G.S., at

King's College, London, on Wednesday and Friday Mornings, from

9 to 10 o'clock, and on Thursday Evenings from 8 to 9, from October

7th, to Christmas, to which the public are admitted on paying the

College Fees, namely, Two Guineas to the Morning Course, and One

Guinea to the Evening.

The Students are accompanied by the Professor to the Museum of

Practical Geology, the British Museum, and other Public institutions,

and also on excursions into the country.

Mr. TENNANT also gives private instruction in Mineralogy and

Geology at his residence, 149, Strand, London, W.C.

THE CHEMICAL NEWS.

VOL. XXIX. No. 564.

BRITISH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

LIVERPOOL MEETING, SEPTEMBER 14, 1870.

INAUGURAL ADDRESS OF THE PRESIDENT,

THOMAS H. HUXLEY, LL.D., F.R.S., &c.,

Professor of Natural History in the Royal School of Mines.

MY LORDS, LADIES, AND GENTLEMEN,—

It has long been the custom for the newly-installed President of the British Association for the Advancement of Science to take advantage of the elevation of the position in which the suffrages of his colleagues had, for the time, placed him, and, casting his eyes around the horizon of the scientific world, to report to them what could be seen from his watch-tower; in what directions the multitudinous divisions of the noble army of the improvers of natural knowledge were marching; what important strongholds of the great enemy of us all, Ignorance, had been recently captured; and, also, with due impartiality, to mark where the advanced posts of science had been driven in, or a long-continued siege had made no progress.

I propose to endeavour to follow this ancient precedent, in a manner suited to the limitations of my knowledge and of my capacity. I shall not presume to attempt a panoramic survey of the world of Science, nor even to give a sketch of what is doing in the one great province of Biology, with some portions of which my ordinary occupations render me familiar. But I shall endeavour to put before you the history of the rise and progress of a single biological doctrine; and I shall try to give some notion of the fruits, both intellectual and practical, which we owe, directly or indirectly, to the working out, by seven generations of patient and laborious investigators, of the thought which arose, more than two centuries ago, in the mind of a sagacious and observant Italian naturalist.

It is a matter of every day experience that it is difficult to prevent many articles of food from becoming covered with mould; that fruit, sound enough to all appearance, often contains grubs at the core; that meat, left to itself in the air, is apt to putrefy and swarm with maggots. Even ordinary water, if allowed to stand in an open vessel, sooner or later becomes turbid and full of living matter.

The philosophers of antiquity, interrogated as to the cause of this phenomena, were provided with a ready and a plausible answer. It did not enter their minds even to doubt that these low forms of life were generated in the matters in which they made their appearance. Lucretius, who had drunk deeper of the scientific spirit than any poet of ancient or modern times except Goethe, intends to speak as a philosopher, rather than as a poet, when he writes that "with good reason the earth has gotten the name of mother, since all things are produced out of the earth. And many living creatures, even now, spring out of the earth, taking form by the rains and the heat of the sun." The axiom of ancient science, "that the corruption of one thing is the birth of another," had its popular embodiment in the notion that a seed dies before the young plant springs from it; a belief so widespread and

so fixed, that Saint Paul appeals to it in one of the most splendid outbursts of his fervid eloquence—

"Thou fool, that which thou sowest is not quickened, except it die."

The proposition that life may, and does, proceed from that which has no life, then, was held alike by the philosophers, the poets, and the people, of the most enlightened nations, eighteen hundred years ago; and it remained the accepted doctrine of learned and unlearned Europe, through the Middle Ages, down even to the seventeenth century.

It is commonly counted among the many merits of our great countryman, Harvey, that he was the first to declare the opposition of fact to venerable authority in this, as in other matters; but I can discover no justification for this widespread notion. After careful search through the "*Exercitationes de Generatione*," the most that appears clear to me is, that Harvey believed all animals and plants to spring from what he terms a "*primordium vegetale*," a phrase which may nowadays be rendered "a vegetative germ;" and this, he says, is "*oviforme*," or "egg-like;" not, he is careful to add, that it necessarily has the shape of an egg, but because it has the constitution and nature of one. That this "*primordium oviforme*" must needs, in all cases, proceed from a living parent is nowhere expressly maintained by Harvey, though such an opinion may be thought to be implied in one or two passages; while, on the other hand, he does, more than once, use language which is consistent only with a full belief in spontaneous or equivocal generation. In fact, the main concern of Harvey's wonderful little treatise is not with generation, in the physiological sense, at all, but with development; and his great object is the establishment of the doctrine of epigenesis.

The first distinct enunciation of the hypothesis that all living matter has sprung from pre-existing living matter, came from a contemporary, though a junior, of Harvey, a native of that country, fertile in men great in all departments of human activity, which was to intellectual Europe, in the sixteenth and seventeenth centuries, what Germany is in the nineteenth. It was in Italy, and from Italian teachers, that Harvey received the most important part of his scientific education. And it was a student trained in the same schools, Francesco Redi—a man of the widest knowledge and most versatile abilities, distinguished alike as scholar, poet, physician, and naturalist—who, just two hundred and two years ago, published his "*Esperienze intorno alla Generazione degli Insetti*," and gave to the world the idea, the growth of which it is my purpose to trace. Redi's book went through five editions in twenty years; and the extreme simplicity of his experiments, and the clearness of his arguments, gained for his views, and for their consequences, almost universal acceptance.

Redi did not trouble himself much with speculative considerations, but attacked particular cases of what was supposed to be "spontaneous generation" experimentally. Here are dead animals, or pieces of meat, says he; I expose them to the air in hot weather, and in a few days they swarm with maggots. You tell me that these are generated in the dead flesh; but, if I put similar bodies, while quite fresh, into a jar, and tie some fine gauze over the top of the jar, not a maggot makes its appearance, while the dead substances, nevertheless, putrefy just in the same way as before. It is obvious, therefore, that the maggots are not generated by the corruption of the meat; and that the cause of their formation must be a something which is kept away by gauze. But gauze will not keep away *aëriform* bodies, or fluids. This something must, therefore, exist in the form of solid particles too big to get through the gauze. Nor is one long left in doubt what these solid particles are; for the blowflies, attracted by the odour of the meat, swarm round the vessel, and, urged by a powerful, but, in this case, misleading instinct, lay eggs, out of which maggots are immediately hatched, upon the gauze. The conclusion, therefore, is unavoidable; the maggots are not generated by the meat, but the eggs

which give rise to them are brought through the air by the flies.

These experiments seem almost childishly simple, and one wonders how it was that no one ever thought of them before. Simple as they are, however, they are worthy of the most careful study, for every piece of experimental work since done, in regard to this subject, has been shaped upon the model furnished by the Italian philosopher. As the results of his experiments were the same, however varied the nature of the materials he used, it is not wonderful that there arose in Redi's mind a presumption that, in all such cases of the seeming production of life from dead matter, the real explanation was the introduction of living germs from without into that dead matter. And thus the hypothesis that living matter always arises by the agency of pre-existing living matter, took definite shape; and had, henceforward, a right to be considered and a claim to be refuted, in each particular case, before the production of living matter in any other way could be admitted by careful reasoners. It will be necessary for me to refer to this hypothesis so frequently, that, to save circumlocution, I shall call it the hypothesis of *Biogenesis*; and I shall term the contrary doctrine—that living matter may be produced by not living matter—the hypothesis of *Abiogenesis*.

In the seventeenth century, as I have said, the latter was the dominant view, sanctioned alike by antiquity and by authority; and it is interesting to observe that Redi did not escape the customary tax upon a discoverer of having to defend himself against the charge of impugning the authority of the Scriptures; for his adversaries declared that the generation of bees from the carcass of a dead lion is affirmed, in the book of Judges, to have been the origin of the famous riddle with which Samson perplexed the Philistines—

"Out of the eater came forth meat,
And out of the strong came forth sweetness."

Against all odds, however, Redi, strong with the strength of demonstrable fact, did splendid battle for *Biogenesis*; but it is remarkable that he held the doctrine in a sense which, if he had lived in these times, would have infallibly caused him to be classed among the defenders of "spontaneous generation." "Omne vivum ex vivo," "no life without antecedent life," aphoristically sums up Redi's doctrine; but he went no further. It is most remarkable evidence of the philosophic caution and impartiality of his mind, that, although he had speculatively anticipated the manner in which grubs really are deposited in fruits and in the galls of plants, he deliberately admits that the evidence is insufficient to bear him out; and he therefore prefers the supposition that they are generated by a modification of the living substance of the plants themselves. Indeed, he regards these vegetable growths as organs, by means of which the plant gives rise to an animal, and looks upon this production of specific animals as the final cause of the galls, and of, at any rate some, fruits. And he proposes to explain the occurrence of parasites within the animal body in the same way.

It is of great importance to apprehend Redi's position rightly; for the lines of thought he laid down for us are those upon which naturalists have been working ever since. Clearly, he held *Biogenesis* as against *Abiogenesis*; and I shall immediately proceed, in the first place, to enquire how far subsequent investigation has borne him out in so doing.

But Redi also thought that there were two modes of *Biogenesis*. By the one method, which is that of common and ordinary occurrence, the living parent gives rise to offspring which passes through the same cycle of changes as itself—like gives rise to like; and this has been termed *Homogenesis*. By the other mode, the living parent was supposed to give rise to offspring which passed through a totally different series of states from those exhibited by the parent, and did not return into the cycle of the parent; this is what ought to be called *Heterogenesis*, the offspring being altogether, and permanently, unlike the parent.

The term *Heterogenesis*, however, has unfortunately been used in a different sense, and M. Milne-Edwards has, therefore, substituted for it *Xenogenesis*, which means the generation of something foreign. After discussing Redi's hypothesis of universal *Biogenesis*, then, I shall go on to ask how far the growth of science justifies his other hypothesis of *Xenogenesis*.

The progress of the hypothesis of *Biogenesis* was triumphant and unchecked for nearly a century. The application of the microscope to anatomy in the hands of Grew, Leeuwenhoek, Swammerdam, Lyonet, Vallisnieri, Reaumur, and other illustrious investigators of nature of that day, displayed such a complexity of organisation in the lowest and minutest forms, and everywhere revealed such a prodigality of provision for their multiplication by germs of one sort or another, that the hypothesis of *Abiogenesis* began to appear not only untrue, but absurd; and, in the middle of the eighteenth century, when Needham and Buffon took up the question, it was almost universally discredited.

But the skill of the microscope-makers of the eighteenth century soon reached its limit. A microscope magnifying 400 diameters was a *chef-d'œuvre* of the opticians of that day; and, at the same time, by no means trustworthy. But a magnifying power of 400 diameters, even when definition reaches the exquisite perfection of our modern achromatic lenses, hardly suffices for the mere discernment of the smallest forms of life. A speck, only 1-25th of an inch in diameter, has, at 10 inches from the eye, the same apparent size as an object 1-10,000th of an inch in diameter, when magnified 400 times; but forms of living matter about the diameter of which is not more than 1-40,000th of an inch. A filtered infusion of hay, allowed to stand for two days, will swarm with living things, among which, any which reaches the diameter of a human red blood-corpuscle, or about 1-3200th of an inch, is a giant. It is only by bearing these facts in mind, that we can deal fairly with the remarkable statements and speculations put forward by Buffon and Needham in the middle of the eighteenth century.

When a portion of any animal or vegetable body is infused in water, it gradually softens and disintegrates; and, as it does so, the water is found to swarm with minute active creatures, the so-called Infusorial Animalcules, none of which can be seen, except by the aid of the microscope; while a large proportion belong to the category of smallest things of which I have spoken, and which must have all looked like mere dots and lines under the ordinary microscopes of the eighteenth century.

Led by various theoretical considerations which I cannot now discuss, but which looked promising enough in the lights of that day, Buffon and Needham doubted the applicability of Redi's hypothesis to the infusorial animalcules, and Needham very properly endeavoured to put the question to an experimental test. He said to himself, if these infusorial animalcules come from germs, their germs must exist either in the substance infused, or in the water with which the infusion is made, or in the superjacent air. Now the vitality of all germs is destroyed by heat. Therefore, if I boil the infusion, cork it up carefully, cementing the cork over with mastic, and then heat the whole vessel by heaping hot ashes over it, I must needs kill whatever germs are present. Consequently, if Redi's hypothesis hold good, when the infusion is taken away, and allowed to cool, no animalcules ought to be developed in it; whereas, if the animalcules are not dependent on pre-existing germs, but are generated from the infused substance, they ought, by and by, to make their appearance. Needham found that, under the circumstances in which he made his experiments, animalcules always did arise in the infusions, when a sufficient time had elapsed to allow for their development.

In much of his work Needham was associated with Buffon, and the results of their experiments fitted in admirably with the great French naturalist's hypothesis of "organic molecules," according to which, life is the inde-

feasible property of certain indestructible molecules of matter, which exist in all living things, and have inherent activities by which they are distinguished from not living matter. Each individual living organism is formed by their temporary combination. They stand to it in the relation of the particles of water to a cascade, or a whirlpool; or to a mould, into which the water is poured. The form of the organism is thus determined by the reaction between external conditions and the inherent activities of the organic molecules of which it is composed; and, as the stoppage of a whirlpool destroys nothing but a form, and leaves the molecules of the water, with all their inherent activities intact, so, what we call the death and putrefaction of an animal, or of a plant, is merely the breaking up of the form, or manner of association, of its constituent organic molecules, which are then set free as infusorial animalcules.

It will be perceived that this doctrine is by no means identical with *Biogenesis*, with which it is often confounded. On this hypothesis, a piece of beef, or a handful of hay, is dead only in a limited sense. The beef is dead ox, and the hay is dead grass; but the "organic molecules" of the beef or the hay are not dead, but are ready to manifest their vitality as soon as the bovine or herbaceous shrouds in which they are imprisoned are rent by the macerating action of water. The hypothesis, therefore, must be classified under *Xenogenesis*, rather than under *Biogenesis*. Such as it was, I think it will appear, to those who will be just enough to remember that it was propounded before the birth of modern chemistry and of the modern optical arts, to be a most ingenious and suggestive speculation.

But the great tragedy of Science—the slaying of a beautiful hypothesis by an ugly fact—which is so constantly being enacted under the eyes of philosophers, was played, almost immediately, for the benefit of Buffon and Needham.

Once more, an Italian, the Abbé Spallanzani, a worthy successor and representative of Redi in his acuteness, his ingenuity, and his learning, subjected the experiments and the conclusions of Needham to a searching criticism. It might be true that Needham's experiments yielded results such as he had described, but did they bear out his arguments? Was it not possible, in the first place, that he had not completely excluded the air by his corks and mastic? And was it not possible, in the second place, that he had not sufficiently heated his infusions and the superjacent air? Spallanzani joined issue with the English naturalist on both these pleas; and he showed that if, in the first place, the glass vessels in which the infusions were contained were hermetically sealed, by fusing their necks; and if, in the second place, they were exposed to the temperature of boiling-water for three-quarters of an hour, no animalcules ever made their appearance within them. It must be admitted that the experiments and arguments of Spallanzani furnish a complete and a crushing reply to those of Needham. But we all too often forget that it is one thing to refute a proposition and another to prove the truth of a doctrine which implicitly, or explicitly, contradicts that proposition; and the advance of science soon showed that, though Needham might be quite wrong, it did not follow that Spallanzani was quite right.

Modern Chemistry, the birth of the latter half of the eighteenth century, grew apace, and soon found herself face to face with the great problems which Biology had vainly tried to attack without her help. The discovery of oxygen led to the laying of the foundations of a scientific theory of respiration, and to an examination of the marvellous interactions of organic substances with oxygen. The presence of free oxygen appeared to be one of the conditions of the existence of life, and of those singular changes in organic matters which are known as fermentation and putrefaction. The question of the generation of the infusory animalcules thus passed into a new phase. For what might not have happened to the organic matter of the infusions, or to the oxygen of the air, in Spallanzani's experiments? What security was there that the development of life which ought to have taken place had not been checked, or prevented, by these changes?

The battle had to be fought again. It was needful to repeat the experiments under conditions which would make sure that neither the oxygen of the air, nor the composition of the organic matter, was altered, in such a manner as to interfere with the existence of life.

Schulze and Schwann took up the question from this point of view in 1836 and 1837. The passage of air through red-hot glass tubes, or through strong sulphuric acid, does not alter the proportion of its oxygen, while it must needs arrest, or destroy, any organic matter which may be contained in the air. These experimenters, therefore, contrived arrangements by which the only air which should come into contact with a boiled infusion should be such as had either passed through red-hot tubes or through strong sulphuric acid. The result which they obtained was, that an infusion so treated developed no living things, while, if the same infusion was afterwards exposed to the air, such things appeared rapidly and abundantly. The accuracy of these experiments has been alternately denied and affirmed. Supposing them to be accepted, however, all that they really proved was, that the treatment to which the air was subjected destroyed *something* that was essential to the development of life in the infusion. This "something" might be gaseous, fluid, or solid; that it consisted of germs remained only an hypothesis of greater or less probability.

Contemporaneously with these investigations, a remarkable discovery was made by Cagniard de la Tour. He found that common yeast is composed of a vast accumulation of minute plants. The fermentation of must, or of wort, in the fabrication of wine and of beer is always accompanied by the rapid growth and multiplication of these *Torulae*. Thus, fermentation, in so far as it was accompanied by the development of microscopical organisms in enormous numbers, became assimilated to the decomposition of an infusion of ordinary animal or vegetable matter; and it was an obvious suggestion that the organisms were, in some way or other, the causes both of fermentation and of putrefaction. The chemists, with Berzelius and Liebig at their head, at first laughed this idea to scorn; but, in 1843, a man, then very young, who has since performed the unexampled feat of attaining to high eminence, alike in Mathematics, Physics, and Physiology—I speak of the illustrious Helmholtz—reduced the matter to the test of experiment by a method alike elegant and conclusive. Helmholtz separated a putrefying, or a fermenting, liquid, from one which was simply putrescible, or fermentable, by a membrane, which allowed the fluids to pass through and become intermixed, but stopped the passage of solids. The result was that, while the putrescible, or the fermentable, liquids became impregnated with the results of the putrescence, or fermentation, which was going on on the other side of the membrane, they neither putrefied (in the ordinary way) nor fermented; nor were any of the organisms which abounded in the fermenting, or putrefying, liquid generated in them. Therefore, the cause of the development of these organisms must lie in something which cannot pass through membrane; and as Helmholtz's investigations were long antecedent to Graham's researches upon colloids, his natural conclusion was that the agent thus intercepted must be a solid material. In point of fact, Helmholtz's experiments narrowed the issue to this: that which excites fermentation and putrefaction, and at the same time gives rise to living forms in a fermentable, or putrescible, fluid, is not a gas and is not a diffusible fluid; therefore, it is either a colloid, or it is matter divided into very minute solid particles.

The researches of Schroeder and Dusch, in 1854, and of Schroeder alone, in 1859, cleared up this point by experiments which are simply refinements upon those of Redi. A lump of cotton-wool is, physically speaking, a pile of many thicknesses of a very fine gauze, the fineness of the

meshes of which depends upon the closeness of the compression of the wool. Now, Schroeder and Dusch found, that, in the case of all the putrefiable materials which they used (except milk and yolk of egg), an infusion boiled, and then allowed to come into contact with no air but such as had been filtered through cotton-wool, neither putrefied nor fermented, nor developed living forms. It is hard to imagine what the fine sieve formed by the cotton-wool could have stopped except minute solid particles. Still the evidence was incomplete until it had been positively shown, first, that ordinary air does contain such particles; and, secondly, that filtration through cotton-wool arrests these particles and allows only physically pure air to pass. This demonstration has been furnished within the last year by the remarkable experiments of Professor Tyndall. It has been a common objection of Abiogenists that, if the doctrine of Biogeny is true, the air must be thick with germs; and they regard this as the height of absurdity. But Nature occasionally is exceedingly unreasonable, and Professor Tyndall has proved that this particular absurdity may, nevertheless, be a reality. He has demonstrated that ordinary air is no better than a sort of strabour of excessively minute solid particles; that these particles are almost wholly destructible by heat; and that they are strained off, and the air rendered optically pure, by being passed through cotton-wool.

But it remains yet in the order of logic, though not of history, to show that, among these solid destructible particles, there really do exist germs capable of giving rise to the development of living forms in suitable menstrua. This piece of work was done by M. Pasteur in those beautiful researches which will ever render his name famous; and which, in spite of all attacks upon them, appear to me now, as they did seven years ago,* to be models of accurate experimentation and logical reasoning. He strained air through cotton-wool, and found, as Schroeder and Dusch had done, that it contained nothing competent to give rise to the development of life in fluids highly fitted for that purpose. But the important further links in the chain of evidence added by Pasteur are three. In the first place, he subjected to microscopic examination the cotton-wool which had served as strainer, and found that sundry bodies, clearly recognisable as germs, were among the solid particles strained off. Secondly, he proved that these germs were competent to give rise to living forms by simply sowing them in a solution fitted for their development. And, thirdly, he showed, that the incapacity of air strained through cotton-wool to give rise to life, was not due to any occult change effected in constituents of the air by the wool, by proving that the cotton-wool might be dispensed with altogether, and perfectly free access left between the exterior air and that in the experimental flask. If the neck of the flask is drawn out into a tube and bent downwards; and if, after the contained fluid has been carefully boiled, the tube is heated sufficiently to destroy any germs which may be present in the air which enters as the fluid cools, the apparatus may be left to itself for any time, and no life will appear in the fluid. The reason is plain. Although there is free communication between the atmosphere laden with germs and the germless air in the flask, contact between the two takes place only in the tube; and as the germs cannot fall upwards, and there are no currents, they never reach the interior of the flask. But if the tube be broken short off where it proceeds from the flask, and free access be thus given to germs falling vertically out of the air, the fluid which has remained clear and desert for months, becomes, in a few days, turbid and full of life.

These experiments have been repeated over and over again by independent observers with entire success; and there is one very simple mode of seeing the facts for oneself, which I may as well describe.

Prepare a solution (much used by M. Pasteur, and

often called "Pasteur's solution") composed of water with tartrate of ammonia, sugar, and yeast-ash dissolved therein.* Divide it into three portions in as many flasks; boil all three for a quarter of an hour; and, while the steam is passing out, stop the neck of one with a large plug of cotton-wool, so that this also may be thoroughly steamed. Now set the flasks aside to cool, and when their contents are cold, added to one of the open ones a drop of filtered infusion of hay which has stood for twenty-four hours, and is, consequently, full of the active and excessively minute organisms known as *Bacteria*. In a couple of days of ordinary warm weather, the contents of this flask will be milky, from the enormous multiplication of *Bacteria*. The other flask, open and exposed to the air, will, sooner or later, become milky with *Bacteria*, and patches of mould may appear in it; while the liquid in the flask, the neck of which is plugged with cotton-wool, will remain clear for an indefinite time. I have sought in vain for an explanation of these facts, except the obvious one, that the air contains germs competent to give rise to *Bacteria*, such as those with which the first solution has been knowingly and purposely inoculated, and to the mould *fungi*. And I have not yet been able to meet with any advocate of Abiogenesis who seriously maintains that the atoms of sugar, tartrate of ammonia, yeast-ash, and water, under no influence but that of free access of air and the ordinary temperature, re-arrange themselves and give rise to the protoplasm of *Bacterium*. But the alternative is to admit that these *Bacteria* arise from germs in the air; and if they are thus propagated, the burden of proof, that other like forms are generated in a different manner, must rest with the assertor of that proposition.

To sum up the effect of this long chain of evidence:—

It is demonstrable, that a fluid eminently fit for the development of the lowest forms of life, but which contains neither germs nor any protein compound, gives rise to living things in great abundance, if it is exposed to ordinary air; while no such development takes place if the air with which it is in contact is mechanically freed from the solid particles, which ordinarily float in it and which may be made visible by appropriate means.

It is demonstrable, that the great majority of these particles are destructible by heat, and that some of them are germs, or living particles, capable of giving rise to the same forms of life as those which appear when the fluid is exposed to unpurified air.

It is demonstrable, that inoculation of the experimental fluid with a drop of liquid known to contain living particles, gives rise to the same phenomena as exposure to unpurified air.

And it is further certain that these living particles are so minute that the assumption of their suspension in ordinary air presents not the slightest difficulty. On the contrary, considering their lightness and the wide diffusion of the organisms which produce them, it is impossible to conceive that they should not be suspended in the atmosphere in myriads.

Thus, the evidence, direct and indirect, in favour of *Biogenesis* for all known forms of life must, I think, be admitted to be of great weight.

On the other side, the sole assertions worthy of attention are, that hermetically sealed fluids, which have been exposed to great and long-continued heat, have sometimes exhibited living forms of low organisation when they have been opened.

The first reply that suggests itself is the probability that there must be some error about these experiments, because they are performed on an enormous scale every day, with quite contrary results. Meat, fruits, vegetables, the very materials of the most fermentable and putrescible infusions are preserved to the extent, I suppose I may say, of thousands of tons every year, by a method which

* Lectures to Working Men on the Causes of the Phenomena of Organic Nature," 1863.

* Infusion of hay, treated in the same way, yields similar results but as it contains organic matter, the argument which follows cannot be based upon it.

is a mere application of Spallanzani's experiment. The matters to be preserved are well boiled in a tin case provided with a small hole, and this hole is soldered up when all the air in the case has been replaced by steam. By this method they may be kept for years, without putrefying, fermenting, or getting mouldy. Now this is not because oxygen is excluded, inasmuch as it is now proved that free oxygen is not necessary for either fermentation or putrefaction. It is not because the tins are exhausted of air, for *Vibrio*nes and *Bacteria* live, as Pasteur has shown, without air or free oxygen. It is not because the boiled meats or vegetables are not putrescible or fermentable, as those who have had the misfortune to be in a ship supplied with unskillfully closed tins well know. What is it, therefore, but the exclusion of germs? I think that Abiogenists are bound to answer this question before they ask us to consider new experiments of precisely the same order.

And in the next place, if the results of the experiments I refer to are really trustworthy, it by no means follows that abiogenesis has taken place. The resistance of living matter to heat is known to vary within considerable limits, and to depend, to some extent, upon the chemical and physical qualities of the surrounding medium. But if, in the present state of science, the alternative is offered us, either germs can stand a greater heat than has been supposed, or the molecules of dead matter, for no valid or intelligible reason that is assigned, are able to re-arrange themselves into living bodies, exactly such as can be demonstrated to be frequently produced in another way, I cannot understand how choice can be, even for a moment, doubtful.

But though I cannot express this conviction of mine too strongly, I must carefully guard myself against the supposition that I intend to suggest that no such thing as abiogenesis ever has taken place in the past, or ever will take place in the future. With organic chemistry, molecular physics, and physiology yet in their infancy, and every day making prodigious strides, I think it would be the height of presumption for any man to say that the conditions under which matter assumes the properties we call "vital" may not, some day, be artificially brought together. All I feel justified in affirming is, that I see no reason for believing that the feat has been performed yet.

And, looking back through the prodigious vista of the past, I find no record of the commencement of life, and, therefore, I am devoid of any means of forming a definite conclusion as to the conditions of its appearance. Belief, in the scientific sense of the word, is a serious matter, and needs strong foundations. To say, therefore, in the admitted absence of evidence, that I have any belief as to the mode in which the existing forms of life have originated, would be using words in a wrong sense. But expectation is permissible where belief is not; and if it were given me to look beyond the abyss of geologically recorded time to the still more remote period when the earth was passing through physical and chemical conditions, which it can no more see again than a man can recall his infancy, I should expect to be a witness of the evolution of living protoplasm from not living matter. I should expect to see it appear under forms of great simplicity, endowed, like existing Fungi, with the power of determining the formation of new protoplasm from such matters as ammonium carbonates, oxalates and tartrates, alkaline and earthy phosphates, and water, without the aid of light. That is the expectation to which analogical reasoning leads me; but I beg you once more to recollect that I have no right to call my opinion anything but an act of philosophical faith.

So much for the history of the progress of Redi's great doctrine of Biogenesis, which appears to me, with the limitations I have expressed, to be victorious along the whole line at the present day.

As regards the second problem offered to us by Redi, whether Xenogenesis obtains, side by side with Homogenesis; whether, that is, there exist not only the ordinary living things, giving rise to offspring which run through

the same cycle as themselves, but also others, producing offspring which are of a totally different character from themselves, the researches of two centuries have led to a different result. That the grubs found in galls are no product of the plants on which the galls grow, but are the result of the introduction of the eggs of insects into the substance of these plants, was made out by Vallisnieri, Reaumur, and others, before the end of the first half of the eighteenth century. The tapeworms, bladderworms, and flukes continued to be a stronghold of the advocates of Xenogenesis for a much longer period. Indeed, it is only within the last thirty years that the splendid patience of Von Siebold, Van Beneden, Leuckart, Küchenmeister, and other helminthologists, has succeeded in tracing every such parasite, often through the strangest wanderings and metamorphoses, to an egg derived from a parent, actually or potentially like itself; and the tendency of inquiries elsewhere has all been in the same direction. A plant may throw off bulbs, but these, sooner or later, give rise to seeds or spores, which develop into the original form.

A polype may give rise to Medusæ, or a pluteus to an Echinoderm, but the Medusa and the Echinoderm give rise to eggs which produce polypes or plutei, and they are therefore only stages in the cycle of life of the species.

But if we turn to pathology it offers us some remarkable approximations to true Xenogenesis.

As I have already mentioned, it has been known since the time of Vallisnieri and of Reaumur, that galls in plants, and tumours in cattle, are caused by insects, which lay their eggs in those parts of the animal or vegetable frame of which these morbid structures are outgrowths. Again, it is a matter of familiar experience to everybody that mere pressure on the skin will give rise to a corn. Now the gall, the tumour, and the corn are parts of the living body, which have become, to a certain degree, independent and distinct organisms. Under the influence of certain external conditions, elements of the body, which should have developed in due subordination to its general plan, set up for themselves and apply the nourishment which they receive to their own purposes.

From such innocent productions as corns and warts, there are all gradations to the serious tumours which, by their mere size and the mechanical obstruction they cause, destroy the organism out of which they are developed; while, finally, in those terrible structures known as cancers, the abnormal growth has acquired powers of reproduction and multiplication, and is only morphologically distinguishable from the parasitic worm, the life of which is neither more nor less closely bound up with that of the infested organism.

If there were a kind of diseased structure, the histological elements of which were capable of maintaining a separate and independent existence out of the body, it seems to me that the shadowy boundary between morbid growth and Xenogenesis would be effaced. And I am inclined to think that the progress of discovery has almost brought us to this point already. I have been favoured by Mr. Simon with an early copy of the last published of the valuable "Reports on the Public Health," which, in his capacity of their Medical Officer, he annually presents to the Lords of the Privy Council. The Appendix to this Report contains an introductory essay "On the Intimate Pathology of Contagion," by Dr. Burdon Sanderson, which is one of the clearest, most comprehensive, and well-reasoned discussions of a great question which has come under my notice for a long time. I refer you to it for details and for the authorities for the statements I am about to make.

You are familiar with what happens in vaccination. A minute cut is made in the skin, and an infinitesimal quantity of vaccine matter is inserted into the wound. Within a certain time, a vesicle appears in the place of the wound, and the fluid which distends this vesicle is vaccine matter, in quantity a hundred- or a thousandfold that which was originally inserted. Now what has taken place in the course of this operation? Has the vaccine

matter by its irritative property produced a mere blister, the fluid of which has the same irritative property? Or does the vaccine matter contain living particles, which have grown and multiplied where they have been planted? The observations of M. Chauveau, extended and confirmed by Dr. Sanderson himself, appear to leave no doubt upon this head. Experiments, similar in principle to those of Helmholtz on fermentation and putrefaction, have proved that the active element in the vaccine lymph is non-diffusible, and consists of minute particles exceeding 1-20,000th of an inch in diameter, which are made visible in the lymph by the microscope. Similar experiments have proved that two of the most destructive of epizootic diseases, sheep-pox and glanders, are also dependent for their existence and their propagation upon extremely small living solid particles, to which the title of *microzymes* is applied. An animal suffering under either of these terrible diseases is a source of infection and contagion to others, for precisely the same reason as a tub of fermenting beer is capable of propagating its fermentation by "infection," or "contagion," to fresh wort. In both cases it is the solid living particles which are efficient; the liquid in which they float, and at the expense of which they live, being altogether passive.

Now arises the question are these microzymes the results of *Homogenesis* or of *Xenogenesis*; are they capable, like the *Torula* of yeast, of arising only by the development of pre-existing germs; or may they be, like the constituents of a nut-gall, the results of a modification and individualisation of the tissues of the body in which they are found, resulting from the operation of certain conditions? Are they parasites in the zoological sense, or are they merely what Virchow has called "heterologous growths?" It is obvious that this question has the most profound importance, whether we look at it from a practical or from a theoretical point of view. A parasite may be stamped out by destroying its germs, but a pathological product can only be annihilated by removing the conditions which give rise to it.

It appears to me that this great problem will have to be solved for each zymotic disease separately, for analogy cuts two ways. I have dwelt upon the analogy of pathological modification, which is in favour of the xenogenetic origin of microzymes; but I must now speak of the equally strong analogies in favour of the origin of such pestiferous particles by the ordinary process of the generation of like from like.

It is, at present, a well-established fact that certain diseases, both of plants and of animals, which have all the characters of contagious and infectious epidemics, are caused by minute organisms. The smut of wheat is a well-known instance of such a disease, and it cannot be doubted that the grape-disease and the potato-disease fall under the same category. Among animals, insects are wonderfully liable to the ravages of contagious and infectious diseases caused by microscopic *Fungi*.

In autumn, it is not uncommon to see flies, motionless upon a window-pane, with a sort of magic circle, in white drawn round them. On microscopic examination, the magic circle is found to consist of innumerable spores, which have been thrown off in all directions by a minute fungus called *Empusa musæ*, the spore-forming filaments of which stand out like a pile of velvet from the body of the fly. These spore-forming filaments are connected with others, which fill the interior of the fly's body like so much fine wool, having eaten away and destroyed the creature's viscera. This is the full-grown condition of the *Empusa*. If traced back to its earlier stages, in flies which are still alive, and to all appearance healthy, it is found to exist in the form of minute corpuscles which float in the blood of the fly. These multiply and lengthen into filaments, at the expense of the fly's substance; and when they have at last killed the patient, they grow out of its body and give off spores. Healthy flies shut up with diseased ones catch this mortal disease and perish like the others. A most competent observer, M. Cohn, who studied

the development of the *Empusa* in the fly very carefully, was utterly unable to discover in what manner the smallest germs of the *Empusa* got into the fly. The spores could not be made to give rise to such germs by cultivation; nor were such germs discoverable in the air, or in the food of the fly. It looked exceedingly like a case of *Abiogenesis*, or, at any rate, of *Xenogenesis*; and it is only quite recently that the real course of events has been made out. It has been ascertained, that when one of the spores falls upon the body of a fly, it begins to germinate and sends out a process which bores its way through the fly's skin; this, having reached the interior cavities of its body, gives off the minute floating corpuscles which are the earliest stage of the *Empusa*. The disease is "contagious," because a healthy fly coming in contact with a diseased one, from which the spore-bearing filaments protrude, is pretty sure to carry off a spore or two. It is "infectious," because the spores become scattered about all sorts of matter in the neighbourhood of the slain flies.

The silkworm has long been known to be subject to a very fatal contagious and infectious disease called the *Muscardine*. Audouin transmitted it by inoculation. This disease is entirely due to the development of a fungus, *Botrytis Bassiana*, in the body of the caterpillar; and its contagiousness and infectiousness are accounted for in the same way as those of the fly-disease. But of late years a still more serious epizootic has appeared among the silkworms; and I may mention a few facts which will give you some conception of the gravity of the injury which it has inflicted on France alone.

The production of silk has been, for centuries, an important branch of industry in Southern France, and in the year 1853 it had attained such a magnitude, that the annual produce of the French sericulture was estimated to amount to a tenth of that of the whole world, and represented a money value of 117,000,000 of francs, or nearly five millions sterling. What may be the sum which would represent the money-value of all the industries connected with the working up of the raw silk thus produced is more than I can pretend to estimate. Suffice it to say that the city of Lyons is built upon French silk, as much as Manchester was upon American cotton before the civil war.

Silkworms are liable to many diseases; and, even before 1853, a peculiar epizootic, frequently accompanied by the appearance of dark spots upon the skin (whence the name of "Pébrine" which it has received), had been noted for its mortality. But, in the years following 1853, this malady broke out with such extreme violence, that, in 1856, the silk-crop was reduced to a third of the amount which it had reached in 1853; and, up till within the last year or two, it has never attained half the yield of 1853. This means not only that the great number of people engaged in silk-growing are some thirty millions sterling poorer than they might have been; it means not only that high prices have had to be paid for imported silkworm-eggs, and that, after investing his money in them, in paying for mulberry-leaves and for attendance, the cultivator has constantly seen his silkworms perish and himself plunged in ruin—but it means that the looms of Lyons have lacked employment, and that, for years, enforced idleness and misery have been the portion of a vast population which, in former days, was industrious and well to do.

In 1858, the gravity of the situation caused the French Academy of Sciences to appoint Commissioners, of whom a distinguished naturalist, M. de Quatrefages, was one, to inquire into the nature of this disease, and, if possible, to devise some means of staying the plague. In reading the Report* made by M. de Quatrefages, in 1859, it is exceedingly interesting to observe that his elaborate study of the Pébrine, forced the conviction upon his mind that, in its mode of occurrence and propagation, the disease of the silkworm is, in every respect, comparable to the cholera among mankind. But it differs from the cholera, and, so far, is a more formidable disease, in being hereditary, and

* "Etudes sur les Maladies Actuelles des Vers à Soie," p. 52.

in being, under some circumstances, contagious as well as infectious.

The Italian naturalist, Filippi, discovered, in the blood of the silkworms affected by this strange disease, a multitude of cylindrical corpuscles, each about 1-6000th of an inch long. These have been carefully studied by Lebert, and named by him *Panhistophyton*; for the reason that, in subjects in which the disease is strongly developed, the corpuscles swarm in every tissue and organ of the body, and even pass into the undeveloped eggs of the female moth. But, are these corpuscles causes or mere concomitants of the disease? Some naturalists took one view and some another; and it was not until the French Government, alarmed by the continued ravages of the malady, and the inefficiency of the remedies which had been suggested, dispatched M. Pasteur to study it, that the question received its final settlement; at a great sacrifice, not only of the time and peace of mind of that eminent philosopher, but, I regret to have to add, of his health.

But the sacrifice has not been in vain. It is now certain that this devastating, cholera-like, Pébrine is the effect of the growth and multiplication of the *Panhistophyton* in the silkworm. It is contagious and infectious because the corpuscles of the *Panhistophyton* pass away from the bodies of the diseased caterpillars, directly or indirectly, to the alimentary canal of healthy silkworms in their neighbourhood; it is hereditary, because the corpuscles enter into the eggs while they are being formed, and, consequently, are carried within them when they are laid; and for this reason, also, it presents the very singular peculiarity of being inherited only on the mother's side. There is not a single one of all the apparently capricious and unaccountable phenomena presented by the Pébrine, but has received its explanation from the fact that the disease is the result of the presence of the microscopic organism, *Panhistophyton*.

Such being the facts with respect to the Pébrine, what are the indications as to the method of preventing it? It is obvious that this depends upon the way in which the *Panhistophyton* is generated. If it may be generated by Abiogenesis, or by Xenogenesis, within the silkworm or its moth, the extirpation of the disease must depend upon the prevention of the occurrence of the conditions under which this generation takes place. But if, on the other hand, the *Panhistophyton* is an independent organism, which is no more generated by the silkworm than the mistletoe is generated by the oak on the apple-tree on which it grows, though it may need the silkworm for its development, in the same way as the mistletoe needs the tree, then the indications are totally different. The sole thing to be done is to get rid of and keep away the germs of the *Panhistophyton*. As might be imagined, from the course of his previous investigations, M. Pasteur was led to believe that the latter was the right theory; and, guided by that theory, he has devised a method of extirpating the disease, which has proved to be completely successful wherever it has been properly carried out.

There can be no reason, then, for doubting that, among insects, contagious and infectious diseases, of great malignity, are caused by minute organisms which are produced from pre-existing germs, or by Homogenesis; and there is no reason, that I know of, for believing that what happens in insects may not take place in the highest animals. Indeed, there is already strong evidence that some diseases of an extremely malignant and fatal character to which man is subject, are as much the work of minute organisms as is the Pébrine. I refer, for this evidence, to the very striking facts adduced by Professor Lister in his various well-known publications on the antiseptic method of treatment. It seems to me impossible to rise from the perusal of those publications without a strong conviction that the lamentable mortality which so frequently dogs the footsteps of the most skilful operator, and those deadly consequences of wounds and injuries which seem to haunt the very walls of great hospitals, and are, even now, destroying more men than die of bullet or bayonet, are due to the importation of minute organisms into wounds, and

their increase and multiplication; and that the surgeon who saves most lives will be he who best works out the practical consequences of the hypothesis of Redi.

I commenced this Address by asking you to follow me in an attempt to trace the path which has been followed by a scientific idea, in its long and slow progress from the position of a probable hypothesis to that of an established Law of Nature. Our survey has not taken us into very attractive regions; it has lain, chiefly, in a land flowing with the abominable, and peopled with mere grubs and mouldiness. And it may be imagined with what smiles and shrugs practical and serious contemporaries of Redi and of Spallanzani may have commented on the waste of their high abilities in toiling at the solution of problems which, though curious enough in themselves, could be of no conceivable utility to mankind.

Nevertheless, you will have observed that, before we had travelled very far upon our road, there appeared, on the right hand and on the left, fields laden with a harvest of golden grain, immediately convertible into those things which the most sordidly practical of men will admit to have value—viz., money and life.

The direct loss to France caused by the Pébrine in seventeen years cannot be estimated at less than fifty millions sterling; and if we add to this what Redi's idea, in Pasteur's hands, has done for the wine-grower and for the vinegar-maker, and try to capitalise its value, we shall find that it will go a long way towards repairing the money-losses caused by the frightful and calamitous war of this autumn.

And, as to the equivalent of Redi's thought in life, how can we over-estimate the value of that knowledge of the nature of epidemic and epizootic diseases, and, consequently, of the means of checking or eradicating them, the dawn of which has assuredly commenced?

Looking back no further than ten years, it is possible to select three (1863, 1864, and 1869) in which the total number of deaths from scarlet fever alone amounted to 90,000. That is the return of killed, the maimed and disabled being left out of sight. Why, it is to be hoped that the list of killed in the present bloodiest of wars will not amount to more than this! But the facts which I have placed before you must leave the least sanguine without a doubt that the nature and the causes of this scourge will, one day, be as well understood as those of the Pébrine are now; and that the long-suffered massacre of our innocents will come to an end.

And thus mankind will have one more admonition that "the people perish for lack of knowledge;" and that the alleviation of the miseries and the promotion of the welfare of men must be sought, by those who will not lose their pains, in that diligent, patient, loving study of all the multitudinous aspects of Nature, the results of which constitute exact knowledge, or Science.

It is the justification and the glory of this great Meeting that it is gathered together for no other object than the advancement of the moiety of Science which deals with those phenomena of Nature which we call physical. May its endeavours be crowned with a full measure of success!

Section B.

ADDRESS TO THE CHEMICAL SECTION.

SEPTEMBER 15, 1870.

By Professor H. E. ROSCOE, Ph.D., F.R.S., President.

GENTLEMEN,—

In the midst of the excitement of the horrible war in which the two most scientific nations of the Continent are now plunged, let us endeavour to turn our thoughts into channels more congenial to the scientific inquirer; and

allow me to recount to you, as far as I am able, the peaceful victories which, since our last meeting in Exeter, have been achieved in our special department of chemistry. But first may I be permitted to draw your attention to the fact that whilst, on the one hand, we hear of professors of chemistry and their students volunteering in the humane offices of field apothecaries or hospital attendants, we learn, on the other hand, that a distinguished chemist has accepted the chairmanship of a scientific committee called together for the express purpose of employing all the resources of modern chemistry in the horrible destruction of their fellow creatures; for to what do such resources in the last instance amount, but to sudden explosion, fire, or poison? The application of such means in such an age as this cannot surely be justified in any sense either by patriotism or public duty. And yet, in spite of all this, it is, in my mind, mainly to the brotherly intercourse of those interested in science and in its applications to the arts and manufactures in different countries that we must look as the small but living fire, which, in the end, will surely serve to melt down national animosities, and to render impossible the breaking out of disasters so fatal to the progress of science and to the welfare of humanity as that of which we are now, unfortunately, the spectators.

With regard to the position of chemical science at the present moment, it will not take a careful observer long to see that, in spite of the numerous important and brilliant discoveries of which every year has to boast, we are really but very imperfectly acquainted with the fundamental laws which regulate chemical actions, and that our knowledge of the ultimate constitution of matter upon which those laws are based is but of the most elementary nature. In proof of this I need only refer to the different opinions expressed by our leading chemists, in a discussion which lately took place at the Chemical Society on the subject of the atomic theory. The president (Dr. Williamson) delivered a very interesting lecture, in which the existence of atoms was treated as "the very life of chemistry." Dr. Frankland, on the other hand, states that he cannot understand action at a distance between matter separated by a vacuous space; and, although, generally granting that the atomic theory explains chemical facts, yet he is not to be considered as a blind believer in the theory, or as unwilling to renounce it if anything better presented itself. Sir B. C. Brodie and Dr. Odling both agree that the science of chemistry neither requires nor proves the atomic theory; whilst the former points out that the true basis of this science is to be sought in the investigation of the laws of gaseous combination or the study of the capacity of bodies for heat, rather than in committing ourselves to assertions incapable of proof by chemical means. Agreeing in the main myself with the opinions of the last chemists, and believing that we must well distinguish between fact and theory, I would remind you that Dalton's discovery of the laws of multiple and reciprocal proportions—I use Dr. Odling's word—as well as the differences in the power of hydrogen replacement in hydrochloric acid, water, ammonia, and marsh gas, are facts, whilst the explanation upon the assumption of atoms is, as far as chemistry is as yet advanced, a theory. If, however, the existence of atoms cannot be proved by chemical phenomena, we must remember that the assumption of the atomic theory explains chemical facts as the undulatory theory gives a clear view of the phenomena of light. Thus, for instance, one of the most important facts and relations of modern chemistry which it appears difficult, if not impossible, to explain without the assumption of atoms, is that of isomerism. How, otherwise than by a different arrangement of the single constituent particles, are we to account for several distinct substances in which the proportions of carbon, hydrogen, and oxygen are the same? Why, for instance, should forty-eight parts by weight of carbon, ten of hydrogen, and sixteen of oxygen united together, be capable of existing as three different chemical sub-

stances unless we presuppose a different statical arrangement of the parts by which these differences in the deportment of the whole are rendered possible? If, then, it be true that chemistry cannot give us positive information as to whether matter is infinitely divisible, and therefore continuous, or consists of atoms and is discontinuous, we are in some degree assisted in this inquiry by deductions from physical phenomena which have been recently pointed out by the genius of Sir William Thomson. He argues from four different classes of physical phenomena, and comes to the conclusion, not only that matter is discontinuous, and, therefore, that atoms and molecules do exist, but he even attempts to form an idea of the size of these molecules, and he states that in any ordinary liquid, transparent or seemingly opaque solid, the mean distance between the centres of contiguous molecules is less than the hundred millionth, and greater than the two-thousand millionth of a centimetre. Or, to form a conception of this coarse-grainedness, imagine a rain-drop or globe of glass as large as a pea, to be magnified up to the size of the earth, each constituent molecule being magnified in the same proportion; the magnified structure would be coarser-grained than a heap of small shuf, but probably less coarse-grained than a heap of cricket balls.

There is, however, another class of physical considerations which render the existence of indivisible particles more than likely. I refer to the mechanical theory of gases by means of which, thanks to the labours of eminent English and German philosophers, all the physical properties of gases, their equal expansion by heat, the laws of diffusion, the laws of alteration of volume under pressure, can be shown to follow from the simple laws of mechanical motion. This theory, however, presupposes the existence of molecules, and in this direction again we find confirmation of the real existence of Dalton's atoms. Indeed, it has been proved that the average velocity with which the particles of oxygen, nitrogen, or common air are continually projected forward, amounts, at the ordinary atmospheric pressure, to 50,000 centimetres per second, whilst the average number of impacts of each of these molecules is 5000 millions per second. The mention of the molecular motions of gases will recall to the minds of all present the great loss which English science has this year sustained in the death of the discoverer of the laws of gaseous diffusion. Throughout his life Graham's aim was the advancement of our knowledge in the special subject of the molecular properties of gases. With this intent he unceasingly laboured up to the moment of his death, in spite of failing health and pressure of official business, unfolding for posterity some of the most difficult as well as the most interesting secrets of nature in this branch of our science. "What do you think," he writes to Hofmann, "of metallic hydrogen, a white magnetic metal?" And yet now, through his labours, the fact of the condensation of hydrogen in the solid state by metallic palladium, and to a less extent by other metals, has become familiar to all of us. Then, again, I would remind you of Graham's recent discovery of the occlusion of hydrogen gas in certain specimens of meteoric iron, whilst earth-manufactured iron contains not hydrogen but absorbed carbonic oxide gas, proving that the meteorite had probably been thrown out from an atmosphere of incandescent hydrogen existing under very considerable pressure, and therefore confirming in a remarkable degree the conclusions to which spectrum analysis had previously led us. The position in the ranks of British science left by Graham's death will not be easily filled up; he accomplished to a certain extent for dynamical chemistry what Dalton did for statical chemistry, and it is upon his experimental researches in molecular chemistry that Graham's permanent fame as one of England's greatest chemists will rest.

As closely connected with the above subjects, I have next to mention a most important research by Dr. Andrews, of Belfast, which, marking an era in the history of gases,

shows us how our oldest and most cherished notions must give way before the touchstone of experiment. No opinion would appear to have been more firmly established than that of the existence of three separate states or conditions of matter, viz., the solid, the liquid, and the gaseous. A body capable of existing in two or more of these states was thought to pass suddenly from one to the other by absorption or emission of heat, or by alterations of the superincumbent pressure. Dr. Andrews has shown us how false are our views on this fundamental property of matter, for he has proved that a large number of, and probably all, easily condensable gases or vapours possess a critical point of temperature at and above which no increase of pressure can be made to effect a change into what we call the liquid state, the body remaining as a homogeneous fluid; whilst below this critical temperature certain increase of pressure always effects a separation into two layers of liquid and gaseous matter. Thus, with carbonic acid, the point of critical temperature is $30.92^{\circ}\text{C}.$, and with each given substance this point is a specific one, each vapour exhibiting rapid changes of volume and flickering movements when the temperature or pressure was changed, but showing no separation into two layers. Under these circumstances, it is impossible to say that the body exists either in the state of a gas or of a liquid; it appears to be in a condition intermediate between the two. Thus, carbonic acid, under the pressure of 108 atmospheres, and at $35.5^{\circ}\text{C}.$, is reduced to the $\frac{1}{430}$ th of the volume which it occupies at one atmosphere, it has undergone a regular and unbroken contraction, and it is a uniform fluid; if we now reduce the temperature below $31^{\circ}\text{C}.$ the liquid condition is assumed without any sudden change of volume or any abrupt evolution of heat. We can scarcely too highly estimate the value of the researches of Andrews.

As examples of the power which modern methods of research give of grappling with questions which only a few years ago were thought to be insoluble, I may quote the beautiful observations, now well known, by which Lockyer determined the rate of motion on the sun's surface, together with those of Frankland and Lockyer respecting the probable pressure acting in the different layers of the solar atmosphere; and lastly, the results obtained by Zöllner, respecting solar physics, and especially the probable absolute temperature of the sun's atmosphere, as well as that of the internal molten mass. These last results are so interesting and remarkable as being arrived at by the combination of recent spectroscopic observation with high mathematical analysis, that I may perhaps be permitted shortly to state them. Starting from the fact of the eruptive nature of a certain class of solar protuberances, Zöllner thinks that the extraordinary rapidity with which these red flames shoot forth proves that the hydrogen of which they are mainly composed must have burst out from under great pressure; and if so, the hydrogen must have been confined by a zone or layer of liquid from which it breaks loose. Assuming the existence of such a layer of incandescent liquid, then applying to the problem the principles and methods of the mechanical theory of gases, and placing in his formulæ the data of pressure and rate of motion as observed by Lockyer on the sun's surface, Zöllner arrives at the conclusion that the difference of pressure needed to produce an explosion capable of projecting a prominence to the height of 30 minutes above the sun's surface, a height not unfrequently noticed, is 4,070,000 atmospheres. This enormous pressure is attained at a depth of 139 geographical miles under the sun's surface, or at that of $\frac{1}{658}$ th part of the sun's semi-diameter. In order to produce this gigantic pressure the difference in temperature between the enclosed hydrogen and that existing in the solar atmosphere amounts to $74,910^{\circ}\text{C}.$ In a similar way Zöllner calculates the approximate absolute temperature of the sun's atmosphere, which he finds to be $27,700^{\circ}\text{C}.$ —a temperature about eight times as high as that given by Bunsen for the oxyhydrogen flame, and

one at which iron must exist in a permanently gaseous form.

Passing on to more purely chemical subjects, we find this year signalled by the re-determination of a most important series of chemical constants, viz., that of the heat of chemical combination, by Julius Thomsen, of Copenhagen. This conscientious experimentalist asserts that the measurements of the heat evolved by neutralising acids and bases hitherto considered most correct, viz., those made with a mercury calorimeter by Favre and Silbermann, differ from the truth by 12 per cent, whilst the determination by these experimenters of the heat of solution of salts is frequently 50 per cent wrong. As the result of his numerous experiments, Thomsen concludes that when a molecule of acid is neutralised by caustic alkali the heat evolved increases nearly proportionally to the quantity of alkali added until this reaches $1, \frac{1}{2}, \frac{1}{3}$, or $\frac{1}{4}$ of a molecule of alkali, according as the acid is mono-, di-, tri-, or tetra- basic. Exceptions to the law are exhibited by silicic, and also partly by boracic, orthophosphoric, and arsenic acids. In the two latter the heat of combination is proportional for the two first atoms of replaceable hydrogen, but much less for the third atom. A second unexpected conclusion which Thomsen draws from his calorific determinations is that sulphuretted hydrogen is a mono-basic acid, and that its rational formula is therefore HSH.

Another important addition made to chemistry since our last meeting is a new, very powerful, and very simple form of galvanic battery, discovered, though not yet described, by Bunsen. In this second Bunsen's battery only one liquid, a mixture of sulphuric and chromic acids, and, therefore, no porous cells, are employed. The plates of zinc and carbon can all be lowered at once into the liquid and raised again at will. The electromotive force of this battery is to that of Grove—the most powerful of known forms—as 25 to 18; it evolves no fumes in working, and can be used for a very considerable length of time without serious diminution of the strength of the current, so that Bunsen writes me that no one who has once used the new battery will ever think of again employing the old forms. I had hoped to be able to exhibit to the section this important improvement in our means of producing a strong current, but war has demanded the use of other batteries, and Bunsen has been unable to send me a set of his new cells.

Amongst the marked points of interest and progress in inorganic chemistry during the past year, we have to notice the preparation of a missing link amongst the oxy-sulphur acids by Schützenberger. It is the lowest known, and may be called hydrosulphurous acid, H_2SO_2 . The sodium salt, NaHSO_2 , is obtained by the action of zinc on the bisulphite; as might be expected, it possesses very powerful reducing properties, and bleaches indigo rapidly. The metallic vanadates have also been carefully examined, and the existence of three distinct series of salts proved, corresponding to the phosphates, viz., the ortho or tribasic vanadates, the pyro or tetrabasic vanadates, and the meta or monobasic vanadates. Of these the ortho salts are most stable at a high temperature, whilst, at the ordinary atmospheric temperature, the meta salts are most stable. In the phosphorus series, as is well known, the order of stability is the reverse; and thus the points of analogy and of difference between phosphorus and vanadium become gradually apparent.

As an illustration of the results of modern organic research—for in viewing the year's progress in this ever widening branch of chemistry it is impossible to do more than give a few illustrations—I may quote Baeyer's remarkable investigations on mellitic acid. Originally discovered by Klaproth in honeystone or mellite (a substance which yet remains the only source of the acid), mellitic was supposed to be a four-carbon acid. Baeyer has quite recently shown that the acid contains twelve atoms of carbon, or has a molecular weight three times as great as was originally supposed. He has shown that mellitic acid is benzohexacarbonic acid, $\text{C}_{12}\text{H}_6\text{O}_{12}$, or

benzol in which the six atoms of hydrogen are replaced by the monad radical, carboxyl (COOH); as benzoic is benzol-mono-carbonic acid, or benzol in which one of hydrogen is replaced by carboxyl. The most interesting portion of Baeyer's research, however, lies in the intermediate acids, partly new and partly acids already prepared, which he has shown lie between mellitic and benzoic acid, and in which from one to six atoms of hydrogen in benzol are respectively replaced by carboxyl. Nor is this all, for he has proved that, with two exceptions, each of these six acids is capable of existing in three isomeric modifications, thus giving us an insight into the arrangement of the molecule of these aromatic compounds. For the simplest mode of explaining these numerous isomers is that given by Baeyer in the different order in which the several atoms of hydrogen in the benzol molecule are replaced. Thus, in the first, or ortho, series, the hydrogen atoms in benzol, being numbered in regular succession, are replaced in the same regular succession; in the second, or meta, series, the order is 1, 2, 3, 5, &c.; whilst the third, or para, series, take open order, as 1, 2, 4, 5, &c. Thus we have—

	Ortho series.	Para series.	Meta series.
$C_{12}H_6O_{12}$ Hexabasic	Mellitic or Benzohexacarbonic.		
$C_{11}H_4O_{10}$ Penta ..	Unknown.		
$C_{10}H_2O_8$ Tetra ..	Pyromellitic or Benzotetracarbonic.	Isopyromellitic.	Unknown.
$C_9H_4O_6$ Tri ..	Trimesinic or Benzotricarbonic.	Hemimellitic.	Trimellitic.
$C_8H_2O_4$ Di ..	Phthalic or Benzodiacarbonic.	Isophthalic.	Tetraphthalic.
$C_7H_2O_2$ Mono..	Benzoic or Benzolmonocarbonic.		

Amongst the most interesting series of new organic bodies are those in which tetrad silicon partly replaces carbon. Our knowledge of these substances is gradually becoming more complete; the last new member prepared by Friedel and Ladenburg is silico-propionic acid—

the first of a series of carbo-silicic acids containing the radical SiO_2H . The interesting researches of Matthiessen and Wright on morphine and codeine have thrown a new light on the constitution of these opium alkaloids. Treated with hydrochloric acid morphine loses one molecule of water, and gives rise to a new base called apomorphine, thus:—

which differs in a remarkable manner from morphine, both in its chemical and physiological actions, being soluble in alcohol, ether, and chloroform, whereas morphine is nearly insoluble, and acting as the most powerful emetic known, one-tenth of a grain producing vomiting in less than ten minutes. Codeine, which only differs from morphine by CH_2 also yields apomorphine on treatment, at a high temperature with hydrochloric acid, methyl chloride being at the same time eliminated.

An important application of the dehydrating and carbon condensing power of zinc chloride, long known in its action on alcohol to produce ether, has been made by Kekulé in the reduplication of aldehyde to form croton aldehyde with loss of water— $2(C_2H_4O) - H_2O = C_4H_6O$. This croton aldehyde is also probably formed as an intermediate product in the manufacture of chloral from aldehyde, and gives rise to the formation of croton chloral, $C_4H_3Cl_3O$.

The discovery of the sedative properties of chloral hydrate by Liebreich marks an era in medical chemistry. The discovery of the anæsthetic properties of chloroform, however, has led to the discovery of the isomerism. How, of the discovery of the anæsthetic properties of the single constituent, but also forms solid alcoholates; for several distinct substances, but also forms solid alcoholates; of carbon, hydrogen, and possess quite different medicinal properties, and it is important that no ten of hydrogen, and sixteen in the official preparation. The discovery of the anæsthetic properties of chloroform, however, has led to the discovery of the isomerism. How, of the discovery of the anæsthetic properties of the single constituent, but also forms solid alcoholates; for several distinct substances, but also forms solid alcoholates; of carbon, hydrogen, and possess quite different medicinal properties, and it is important that no ten of hydrogen, and sixteen in the official preparation.

an enormous impetus in the practical working of the brilliant discovery of the production of artificial alizarine, the colouring matter of madder, by Messrs. Graebe and Liebermann. This discovery, announced at our last meeting, is of the highest importance—whether we regard its scientific interest or its practical and commercial value—and it differs from all the former results which have been brought about by the application of science to the production of colouring matter, inasmuch as this has reference to the artificial production of a natural vegetable colouring substance, which has been used as a dye from time immemorial, and which is still employed in enormous quantities for the production of the pink, purple, and black colours which are seen everywhere on printed calicoes. During the past year much progress has been made in the practical working of the processes by which this colouring matter is obtained from the hydrocarbon anthracene contained in coal tar, and new and more economical plans for effecting the transformation have been independently proposed by Perkin and Caro, and Schorlemmer and Dale. The theoretical investigation of the reaction—and especially of the nature of some other peculiar products formed in addition to alizarine, which render the artificial colouring matter different from natural alizarine—has been carried out by Mr. Perkin, and especially by Dr. Schunck. As we are promised papers on this subject from both these gentlemen, I need not at present enter further into these interesting questions.

The surest proof of perfection in a manufacture is the degree in which the waste products are utilised, and in which the processes are made continuous. One by one the imperfections of the original discovery are made to disappear, and the products which were wasted become sources of profit, whilst in many cases their utilisation alone renders possible the continuance of the manufacture in the midst of a rapidly increasing district. The section will have the opportunity of inspecting the practical working of at least two of the most valuable of these new processes which have lately been introduced into our most important chemical manufacture—that of alkali. The first of these has been at work for some time, it is that of the recovery of sulphur from the vat waste, that *bête noir* of the alkali makers and of their neighbours. Dr. Mond has now, I believe, satisfactorily solved the difficult problem of economically regaining the sulphur by oxidising the insoluble monosulphide of calcium in the lixiviating vat itself to the soluble hyposulphite, and decomposing this by hydrochloric acid when all the sulphur is deposited as a white powder. The second of these discoveries relates to the recovery or regeneration of the black oxide of manganese used for the evolution of chlorine in the manufacture of bleaching powder. This subject has long attracted the attention of chemists, and a feasible, though somewhat costly, process, that of Dunlop, has been at work for some time at Messrs. Tennant's work at St. Rollox. During the last year a very beautifully simple and economical process proposed by Mr. Weldon, and first successfully carried out on a practical scale at Messrs. Gamble's works at St. Helens, has quickly obtained recognition, and is now worked by more than thirty-seven firms throughout the kingdom. The principle upon which this process depends was explained by Mr. Weldon at the Exeter meeting. It depends on the fact that although when alone the lower oxides of manganese cannot be oxidised by air and steam under the ordinary pressure to the state of binoxide, yet that this is possible when one molecule of lime is present to each molecule of oxide of manganese. The manganous oxide is precipitated from the still liquors with the above excess of lime, and by the action of steam and air on this, a black powder, consisting of a compound of manganese, dioxide and lime, MnO_2CaO , or calcium manganite, is formed. This, of course, is capable of again generating chlorine on addition of hydrochloric acid, and thus the chlorine process is made continuous with a working loss of only 2½ per cent of manganese. The section will have the advantage of seeing Mond's

process at work at Messrs. Hutchinson's, and Weldon's process at Messrs. Gaskell, Deacon, and Co., at Widnes. A third process, which may possibly still further revolutionise the manufacture of bleaching powder, is the direct production of chlorine from hydrochloric acid without the use of manganese at all. In presence of oxygen and of certain metallic oxides, such as oxide of copper, hydrochloric acid gas parts at a red heat with all its hydrogen, water and chlorine being formed. This interesting reaction is employed by its discoverer, Mr. Deacon, for the direct manufacture of bleaching powder from the gases issuing directly from the salt-cake furnace. Air is admitted together with hydrochloric acid gas, and the mixture is passed over red-hot bricks, impregnated with copper salt. The oxide of copper acts as by contact and remains unaltered, whilst the chlorine, watery vapour, and excess of air pass at once into the lime chamber. There are many practical difficulties in working this process, some of which have still to be overcome, but I believe we shall hear from Mr. Deacon that, notwithstanding this drawback, he has accomplished his end of making good bleaching powder by this process.

GERMAN CHEMICAL SOCIETY OF BERLIN.

THE Editor has just received the following letter and communication from Dr. Hofmann. No introductory remarks from us are needed to urge the vital importance of a liberal and speedy response to this appeal of the German chemists to their English brethren.

MY DEAR MR. CROOKES.—Could you find space for the annexed appeal in your columns. If you were to introduce the subject by some prefatory remarks, you would greatly oblige—Yours most sincerely,

A. W. HOFMANN.

Berlin, September 11th, 1870.

The encampments of our armies in the present war; the fortresses where enormous numbers of troops, many of them badly fed and wounded, are crowded within spaces altogether inadequate; the hospitals, lastly, which, to satisfy the pressing demand, are rapidly being established all over Germany, Alsace, and Lorraine, are apt to become the hotbeds of all sorts of contagious poison. A host of new enemies threaten to arise from these places, in the form of fever and diseases of every description; and to the sudden terror of battle will be added the formidable burden of protracted suffering, unless the precautionary measures which science suggests be adopted with the utmost speed and to the fullest extent.

Animated by the desire to avert, as far as possible, such calamities, the Council of the German Chemical Society of Berlin have associated themselves with the Central Committee for the Relief of Sick and Wounded Soldiers in the Field, and now appeal to all chemical manufacturers for help in procuring an early supply of disinfectants on a very scale.

With the view of accomplishing this object, the Council of the German Chemical Society venture to hope that also many of the British manufacturers may feel disposed to co-operate with them, by placing at their disposal, either in one delivery or by regular instalments, a supply of the undermentioned disinfectants.

By order of the Council,

A. W. HOFMANN.

All communications to be addressed to Professor Hofmann, care of Dr. Wichelhaus, 33, Georgen Str., Berlin.

List of Disinfectants.

1. Liquid residues of the manufacture of chlorine.
2. Chloride of lime.
3. Green vitriol.
4. Permanganate of potash.
5. Carbolic acid (crude and purified).

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Comptes Rendus des Séances de l'Académie des Sciences, September 5, 1870.

Most of the original memoirs and papers published in this number refer to natural history and mathematical subjects; those relating to physico-chemical matters are the following:—

Mariotte's Theory of Barometrical Oscillations.—W. de Fonvielle.—The author states that, at page 161 of the first volume of the "Oeuvres de Mariotte," published at Paris in 1740 the following ingenious theory is propounded, with the view to explain why the mercury in a barometer-tube rises with a prevailing northerly wind, and falls when it blows from the south-east. "The action of the north and north-east wind is not simply due to the fact that they render the air heavier (no doubt in consequence of its contraction by cold—W. de F.), but also because they blow against the globe, in the direction of from top to bottom; and, by thus compressing the air, increase its elasticity, whereby the mercury is lifted up. The barometric oscillations which are observed when a southerly or south-west wind prevails are explained on an analogous principle, viz.—The south and south-west winds coming from afar blow towards the globe in a tangential direction, thereby lifting the upper layers of the air, and consequently diminishing its elasticity below, and thereby causing the mercury in the barometer-tube to fall."

Chemical Composition of Nadorite.—M. Flajolot.—The author has made a new series of analyses of this mineral, which he now finds to have the following per cental composition:—Lead, 51.60; antimony, 32.25; oxygen, 8.00; chlorine, 8.85. Formula, $\text{Sb}_2\text{O}_3\text{Cl}_2\text{PbO}$. The mineral may be considered to consist of a combination of oxide of lead and oxychloride of antimony—viz., 55.6 of oxide of lead and 43.4 of oxychloride of antimony, $\text{Sb}_2\text{O}_3\text{Cl}$.

Essay on the Venom of Scorpions.—Dr. Jousset.—This lengthy memoir contains the detailed account of a series of experiments on the venom of the *Scorpio occitanus*, a rather common *Arachnida* in Southern Europe. The author draws, from his experiments, the following conclusions:—The venom of the *Scorpio occitanus* acts directly and solely upon the red blood globules. This action consists in withdrawing from the globules their property of gliding over each other. By losing this property, the blood globules become glued together, and, by thus becoming an adhesive mass, obstruct the circulation of blood in the capillary portion of the vascular system, thereby causing a stasis which is altogether incompatible with the proper conditions of life. The author also observes that, since the action of the scorpion's venom is purely chemical, and that a certain quantity of it (the venom) is required for exerting its action, it essentially differs from virus, which acts as a ferment.

Gunpowder Prepared with Chlorate of Potassa.—M. Zaliwski.—The author proposes to render this powder fit for fire-arms, by mixing with it some finely-pulverised oxalic acid. The manufacture of gunpowder wherein, instead of the whole or part of the nitre, chlorate of potassa was introduced was tried in France as far back as the year 1788, at Essone, by the advice of M. Berthollet; but, at the first trial of mixing the materials (sulphur, charcoal, and chlorate of potassa), a tremendous explosion took place, whereby several people were killed. Afterwards (1793), some of this powder was successfully prepared, and tried in fire-arms, but it was found to be dangerous, in consequence of its great tendency to explode, by slight concussion even; and its action is comparable to that of the fulminates, which, as is well known, are not at all suitable to serve as substitutes for powder. The author's idea of rendering chlorate of potassa gunpowder fit for use, by the addition of pulverised oxalic acid, will be further investigated by a committee of scientific men.

Moniteur Scientifique, No. 329, September 1, 1870.

This number contains the following original matter relating to chemistry and collateral sciences:—

Detection of Strychnia in Medico-Forensic Analysis.—Dr. Weyrich.—The author relates, at great length, a case of poisoning, with strychnia, of a person accustomed to consume opium, and to whom had been given large doses of ipecacuanha, while, moreover, a portion of the contents of the intestines had to be tested for mineral poisons. The real bearing, therefore, of this case turns upon the detection of strychnia in the presence of emetine and morphia. The strychnia was detected in an alcoholic extract of the materials taken from the corpse, by means of the reaction produced by strong sulphuric acid and bichromate of potassa, which at first oxidises only the emetine, and, this having been removed, produces the well-known purple colour—

tion, due to the action of the bichromate and sulphuric acid upon strychnia. The morphia was detected in a separately-made allylic alcoholic solution, by means of molybdate of soda in dissolved concentrated sulphuric acid.

Detection of the Adulteration of Quinine with Salicine.—Dr. Sonelén.—The author has comparatively tested the degree of accuracy and sensitiveness of the different tests in use for the detection of the presence of salicine in quinine, which, if made with the view of fraudulent adulteration, will always be at least at the rate of 1 per cent of salicine, or more, because less will not pay. The author employed three kinds of sulphuric acid—viz., the fuming, pure concentrated acid, free from arsenic and nitric acid; ordinary concentrated sulphuric acid of commerce, containing a trace of nitric acid; and, lastly, sulphuric acid to which, purposely, nitric acid had been added. A watch-glass having been placed on a sheet of white paper, and a drop or two of the acids above referred to (each in a separate glass) having been poured therein, a few crystals of the alkaloid (sulphate of quinine) were put on the acid; if pure, there is no colouration, but, even with 1-100th of salicine, the three first-named acids caused a distinct red colouration, which did not ensue with the acid containing nitric acid. This latter acid was not even coloured by pure salicine.

Permeability of the Skin for Liquids.—Dr. Bloch.—The author describes a series of experiments made with divers fluids, none of which could exert any chemical or physical action upon the skin. Bordeaux wine, having been experimented with, was found to have penetrated the skin of the arm, washed and wiped dry, after it had been immersed for one hour in the wine, since, on washing the arm with a weak solution of perchloride of iron, the skin was black-coloured, owing to the formation of a tannate. The author seems to have forgotten that the permeability of the skin for liquids is employed in medicine as a therapeutic agent. We recollect the case of a lady who bathed in chicken broth twice daily, for therapeutic purposes; and milk, also, is in this way introduced into, and absorbed by, the system.

Zeitschrift für Chemie von Beilstein, No. 13, 1870.

This number contains the following original papers and memoirs:—

Analysis of the Water of Two Mineral Springs situated in the Neighbourhood of Cairo (Egypt).—Dr. C. Bender.—Water from Ain-Syra contains, in 1000 grms., 11.892 grms. of solid matter and 0.048 grms. of free carbonic acid gas. The solid matter, in grammes, is—Chloride of calcium, 0.150; chloride of magnesium, 1.850; chloride of sodium, 5.963; sulphate of lime, 0.590; sulphate of magnesia, 3.420; carbonate of lime, 0.004; carbonate of protoxide of iron, 0.005; traces of alumina and organic matter. Water from Helwan, in 1000 grms., contains—Gases—Sulphuretted hydrogen, 0.044; free carbonic acid, 0.012; nitrogen, a trace. Solid substances, in grms.—Chloride of calcium, 0.180; chloride of magnesium, 1.820; chloride of sodium, 3.200; sulphate of lime, 0.024; carbonate of lime, 0.050; organic matter, a trace.

Action of Pentabromide of Phosphorus upon Azoxybenzide.—A. Weigé.—The author, desirous of substituting bromine for the oxygen contained in azoxybenzide, caused pentabromide of phosphorus to act upon azoxybenzide, and obtained (care being taken to moderate the violence of the reaction which takes place) a yellow-coloured crystalline substance, $C_{10}H_6N_2Br_5$. This body is, however, very unstable, so that it is even partly decomposed while being dissolved in sulphide of carbon, as well as in alcohol. By careful manipulation, the author was enabled to ascertain that the body referred to fuses at 70° , and then becomes deep red-coloured, but, on cooling, reassumes its former yellow colour. Finely-divided silver withdraws the bromine from this compound, leaving azobenzide.

On Brom-Benzol-Sulphochloride, its Derivatives; and on the Position Hydrogen Occupies in Benzol.—H. Hübler and L. Alsberg.—The authors describe—Brombenzol-sulphochloride, $C_6H_5BrSO_2Cl$, a beautifully-crystalline compound, fusing at about 70° . Monobrombenzol-sulphohydrate, C_6H_5BrSH ; volatile when carried by steam; soluble in boiling alcohol; crystalline akin to naphthalene; fuses at 75° ; precipitated from its alcoholic solution by acetate of lead. Monobrombenzol-disulphide—

fuses at 93.5° , is very difficultly soluble in alcohol, and not precipitated by acetate of lead. Benzol-sulphohydrate, C_6H_5SH ; a liquid boiling at about 167° ; highly refracting light; smelling like mercaptan.

Sulpho-Acids and Sulpho-Hydrates derived from Crystallised Bromotoluol.—H. Hübler and J. Post.—This paper contains a lengthy enumeration of α , β , and γ series of sulpho-salts of bromotoluol, and the lengthy review of the toluol-sulpho hydrates obtained from α and β bromotoluol-sulphoacid.

Preparation of Naphthæ Acid on the Large Scale.—V. Merz and H. Noll.—The authors describe, at great length, a series of experiments, chiefly instituted with the view to obtain naphthæ acid by a cheap and expedient process readily executable on the large scale, so as to produce, from naphthalene, the acid referred to, in sufficient quantities to employ that acid industrially instead of benzoic acid. The process of preparation is, briefly, the following:—Sulpho-naphthalates, best alkaline, are distilled with cyanide of potassium, and the product of that distillation is saponified, yielding about four-fifths of its weight of naphthæ acid, which, however, requires a rather lengthy and tedious process of purification.

Preliminary Notice on the Action of Phosgen upon some of the Amides.—H. Schmidt.—When fluid phosgen acts, at 100° , upon urea, there is obtained a compound which the author calls carbonyl-dicarbamide, according to the formula—

When this body is again heated, along with phosgen, up to 160° – 170° , there is formed dicyanide acid; when phosgen acts upon benzamide, at about 165° , there are formed benzoyl-chloride, benzo-nitrile, kypahenin, carbonic acid, and chloride of ammonium.

On Allyl-Cyanide.—A. Rinne and B. Tollens.—The authors confirm the statements made by MM. Kekulé, Gautier, and others, as regards the reaction which takes place when chloride of allyl, dissolved in allylic alcohol, is put, along with cyanide of potassium, in a sealed tube, and heated to 100° . When the chloride of allyl, not in allylic alcoholic solution, is heated, in a sealed tube, to a higher temperature, a fluid is obtained which boils between 100° and 120° , but which has not been further investigated, since the authors only operated upon small quantities of material, and intend extending and continuing these researches.

New Derivatives from Toluol.—A. Heyneman.—The author describes paraolmeta-nitrotoluol, nitrate of paraolmeta-toluidine, parabrommeta-toluidine, binitro-iodkresol, and parabrom-nitrotoluol.

Polytechnisches Journal von Dingler, second number for July, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Power of Electro-Magnets for Lifting Weights.—Dr. A. von Waltenhofen.—The author describes a series of experiments, instituted with the view of elucidating the question of the hitherto-conflicting results obtained in reference to the relation the lifting power of an electro-magnet bears to the force of the electric current. The experiments made by the author lead to the result that a retention, or keeping back, of lifting power, after the electric current has ceased to act, does set in with forces of currents which are within the limits of the Lenz-Jacobi's law; while, on the other hand, a forerunning (Vorzeiten) of lifting power is limited to, comparatively, very weak currents.

Electro-Magnetic Behaviour of Discontinuous Masses of Iron; and—

Description of an Apparatus for Demonstrating the Magnetic Behaviour of Iron Tubes.—By the same author as the first-named paper.—Are memoirs illustrated with engravings.

Contribution to the History of Continuous Annular-Shaped Brick-Kilns.—P. Loeff.—With engravings.

Santorin Earth.—Dr. G. Feichtinger.—The material known as Santorin earth is a native product of the Island of Santorin, situated in the Mediterranean Sea, and part of the Greek territory. This earth, dried at 100° , consists, in 100 parts, of:—a. (substances soluble in water)—Sulphate of lime, 0.05; chloride of sodium, 0.05. b. (soluble in hydrochloric acid)—Alumina, 1.36; peroxide of iron, 1.34; lime, 0.34; magnesia, 0.23; silica, 3.40. c. (insoluble in hydrochloric acid)—Silica, 66.37; alumina, 12.36; peroxide of iron, 2.90; lime, 2.53; magnesia, 1.06; potassa, 2.83; soda, 4.22; water (only eliminable at low red heat), 4.06—Total, 99.83. The substance alluded to is used, along with lime, to form an excellent hydraulic cement; and the bulk of the contents of this paper are devoted to quote a series of researches bearing upon the subject of the hydraulic cements.

Estimation of Sulphur, Phosphorus, and Silicium present in Pig-Iron.—Dr. E. Richtera.—This paper contains a comparative review of the relative values of the methods of Lippert and Gintl for the quantitative estimation of the substances referred to. The methods alluded to are fully described in the last edition of Fresenius's excellent work. The result of the author's researches is that Gintl's method is excellent for sulphur and phosphorus, but gives the silicium rather too low.

Manufacture of Spirit from Moss and Lichens.—S. Stenberg and T. Stahlschmidt.—This subject is by no means unimportant, since it may lead to the substitution for grain (if not completely, at least partly), as spirit-yielding material, of the abundance of mosses and lichens found in wild state on land, as well as in the sea. This lengthy paper contains a full description of the process of converting the cellulose and starch present in the raw materials into glucose.

Preparation of Beer so as to make it Fit for Long Journeys by Sea.—Dr. E. Dingler.—This essay is illustrated with engravings.

Spontaneous Combustion of Black-Dyed Silk.—Dr. E. Dingler.—A short time ago, a fire broke out at the premises of MM. Be-hague and Payer, Paris, who are wholesale silk merchants; the fire was, however, very quickly discovered, and this gave rise to the discovery that it originated inside a large parcel of black-dyed silk which had been returned from the dye-house only twenty-four hours previously. That black-dyed silk is rather liable to spontaneous combustion, has been a well-known fact for years, but, notwithstanding the researches of Persoz and others on this subject, the real cause is not quite elucidated. It is advisable, however, not to keep large quantities of black-dyed silk together, and, also, to prevent it getting very dry; and, above all, care should be taken to prevent it being exposed to any great degree of heat, while proper ventilation among the parcels should be also attended to.

THE CHEMICAL NEWS.

VOL. XXII. No. 563.

ON THE MANUFACTURE OF CHLORINE.*

By WALTER WELDON.

At the meeting of this Section at Exeter, last year, I had the honour to describe a process for the manufacture of chlorine by means of a perpetually regenerated reagent consisting mainly of a previously unknown compound containing the elements of peroxide of manganese and lime. At that time the process in question was at work only at two places. It had been in operation for about a year at the works of Lieut.-Colonel Gamble, at St. Helens, at whose works, and by whose very generous co-operation, the process had been wrought out; and it has just begun to be adopted by Messrs. Gaskell, Deacon, and Co., at Widnes. It is now in operation at ten works in this country; in a few weeks it will be in operation in sixteen works in this country; at eight or nine other works in this country the erection of plant for it has either already begun or is on the point of beginning; with the exception of a very few of the very smallest, every British manufacturer of chlorine has taken a licence for the use of it; the principal continental manufacturers have done the same; and large plants for it are already completed both in France and in Germany, and, although not yet at work, would have been some time ago but for the interruption of all ordinary industrial occupations which has been occasioned in those countries by the war. In view of the extent to which this process thus has been and is being adopted, and of the probable completeness of the revolution which it is effecting in the mode of manufacturing an important commodity which is very largely produced in the district in which we are now assembled, Dr. Roscoe has suggested that I should this year submit to the Section a brief account of the practical results which the process has been found to yield under the more extended experience which we have now had of it, and of the development which it has undergone since the date of my paper of last year.

The process is performed by means of an apparatus of which I exhibit a model. The vessels comprised in this apparatus are arranged at five successive elevations, so that after having been pumped up to the highest of them the liquor operated upon can afterwards descend to all the others by its own gravity. The lowest of these vessels is a well, which is furnished with a mechanical agitator. The slightly acid chloride of manganese liquor with which the process commences runs from the stills in which it is produced into this well, and is there treated with finely-divided carbonate of lime, the action of which is facilitated by energetic agitation. When the neutralisation of the free acid which is at first contained in this liquor, and the decomposition of the sesquichloride of iron and sesquichloride of aluminium which are also at first contained in it, are completed, the liquor is pumped up into settling tanks placed nearly at the top of the apparatus, and known as the "chloride of manganese settlers." It now consists of a quite neutral mixed solution of chloride of manganese and chloride of calcium, containing in suspension considerable quantities of sulphate of lime and small quantities of oxide of iron and alumina. These solid matters rapidly deposit in the chloride of manganese settlers, leaving the bulk of the liquor perfectly bright and clear, and of a faint rose colour. The next step is to run off the clear portion of the contents of the chloride of manganese settlers into a vessel placed immediately below those settlers, and called the "oxidiser." This is usually a cylindrical iron vessel about 12 feet in diameter and about

22 feet deep. Two pipes go down nearly to the bottom of the oxidiser—a large one for conveying a blast of air from a blowing-engine, and a smaller one for the injection of steam. The latter is for the purpose of raising the temperature of the contents of the oxidiser when necessary—for sometimes the chloride of manganese liquor reaches the oxidiser sufficiently hot—to somewhere between 130° and 160° or 170° F. Immediately above the oxidiser is a reservoir containing milk of lime. The oxidiser having received a charge of clear liquor from the chloride of manganese settlers, and this liquor having been heated up to the proper point, if it was not already hot enough, blowing is begun, and milk of lime is then run into the oxidiser as rapidly as possible, until the filtrate from a sample taken at a tap placed nearly at the bottom of the oxidiser ceases to give a manganese reaction with solution of bleaching-powder. A certain further quantity of milk of lime is then added, and the blowing is then continued until peroxidation ceases to advance. That point is usually attained when from about 80 to 85 per cent of the manganese present has become converted into peroxide. The contents of the oxidiser are now a thin black mud, consisting of solution of chloride of calcium containing in suspension about two pounds of peroxide of manganese per cubic foot, these two pounds of peroxide of manganese being combined with varying quantities of protoxide of manganese and lime. This thin mud is now run off from the oxidiser into one or other of a range of settling-tanks ("mud settlers") placed below it, and is there left at rest until it has settled as far as it will, usually until about one-half of its volume has become clear. The clear part, consisting simply of solution of chloride of calcium, is then decanted, and the remainder, containing about four pounds of peroxide of manganese per cubic foot, is then ready to be used in the stills. There it reacts upon hydrochloric acid, liberating chlorine, with reproduction of exactly such a residual solution as was commenced with. With that solution the round of operations is begun again; and so on, time after time, indefinitely.

The quantity of lime which has to be put into the oxidiser before the filtrate from a sample of its contents ceases to give a manganese reaction, varies very considerably. Recently precipitated protoxide of manganese dissolves very appreciably in neutral solution of chloride of calcium, its solution therein comporting itself with reagents, exactly like solutions of manganese salts. It dissolves also in solution of oxychloride of calcium, that is to say, in solution of chloride of calcium containing dissolved lime; its solution in oxychloride of calcium not giving the ordinary manganese reactions. Hence, even if all portions of the lime added to the chloride of manganese in the oxidiser were capable of acting on chloride of manganese equally readily, manganese could not cease to be so in solution as to be detectable by ordinary reagents until more than an equivalent of lime had been added,—until enough had been added, that is to say, not only to decompose all the chloride of manganese, but also to form a certain quantity of oxychloride of calcium. It is never the case, however, that all portions of the lime used are capable of acting on the chloride of manganese with equal readiness. The lime used always contains a larger or smaller proportion of particles coarser than the rest, which coarser portions cannot of course act so rapidly as the finer portions; and as the decomposition of the chloride of manganese requires to be completed as quickly as possible, those portions of the lime which will not act upon it instantly are scarcely allowed time to act upon it at all. These coarser portions of the lime thus contribute very little to the decomposition of the chloride of manganese, though they afterwards dissolve completely in the hot solution of chloride of calcium, and then play their full part in the reactions which take place during the subsequent blowing. The proportion of the lime which thus does not act on the chloride of manganese varies with the source of the lime, and with the manner in which it is prepared; so that the quantity of lime which has to be added

* Read before the British Association, Liverpool Meeting, Section B.

to a charge of chloride of manganese liquor in the oxidiser before the filtrate from a sample of the resulting mixture ceases to become coloured on addition of solution of bleaching-powder, varies from about 1.15 to 1.45 equivalents. The further quantity of lime which is added after that point has been reached is now usually simple enough to raise the total quantity to about 1.5 or 1.6 equivalents, being from one-half to six-tenths in excess of the quantity which actually takes part in the decomposition of the chloride of manganese.

The results which we have latterly begun to obtain with these proportions of lime are such as our previous experience had not prepared us to expect. Until quite recently, our experience seemed to show that whatever proportions of lime we might use in the oxidiser, we could not obtain products containing less than an equivalent of base or bases per equivalent of peroxide of manganese in them. Now, however, we are regularly obtaining products containing only between 0.9 and 0.7 equivalents of base, and we have occasionally got down nearly to 0.5 equivalents of base. With respect to the conditions which determine the formation of products containing these low proportions of base, all that I can say at present is that we have begun to make these products, or at any rate to make them regularly, only since we began to considerably increase the quantity of air blown in a given time into an oxidiser of a given size. There can be scarcely any doubt now that products containing at any rate something less than an equivalent of base have been made occasionally, under special circumstance, from the very beginning; but for a long time it was only so very rarely that we seemed to get less than an equivalent of base, and the apparent proportion less than an equivalent was always so small, that we put down the apparent result—a little hastily, as it now appears—to errors of analysis. It is certain, however, that products containing appreciably less than an equivalent of base have begun to be made regularly only since manufacturers who had previously employed only one blowing-engine for the process began to use two engines, blowing with both into the same oxidiser, and since other manufacturers began to work with larger blowing-engines than had been used in the process before.

All that I can learn with respect to the composition of the new products containing less than an equivalent of base tends to show, to my mind, that there are manganites corresponding to nearly all the known carbonates. We knew last year of normal manganites, corresponding, say, to normal carbonate of calcium, and of basic manganites, corresponding to Schindler's carbonate of zinc and to Bonsdorf's carbonate of lead. I venture to believe now that there are also acid manganites, corresponding to the bicarbonates, and that sesquimanganites probably exist as well.

That hydrated peroxide of manganese, or H_2MnO_3 , is as distinctly an acid as H_2CO_3 , or H_2SO_3 , seems to me to be shown by the fact that if free hydrated peroxide of manganese be boiled with an equivalent of protoxide of manganese, a reaction takes place between the two bodies, the product of which reaction does not absorb oxygen on treatment with air. Of course, if any free MnO remained after boiling the two bodies together, oxygen would be absorbed on subsequent treatment with air. The product is, in fact, precisely the same compound—ordinarily called "sesquioxide of manganese," and written Mn_2O_3 —as that which is produced by blowing air into a mixture of protoxide of manganese and water, or in any other way exposing protoxide of manganese, by itself, to the action of the atmosphere at ordinary temperatures; and its formation in the way just stated seems to me to be exactly similar to that, say, of carbonate or of sulphite of calcium by the reaction of H_2CO_3 or of H_2SO_3 upon CaO . Apart from its being thus formed by a reaction exactly resembling the ordinary reaction of an acid upon a basic protoxide, that which is ordinarily called sesquioxide of manganese is really manganite of hydrogen in which H_2 has been

replaced by Mn , and that it is thus properly manganite or manganese, or $MnMnO_3$, seems to me to follow from the circumstance that, by whatever method this body may have been produced, on treating it with solution of certain salts of other metals ordinary double decompositions occur. Thus, $MnMnO_3 + CuSO_4$ give $MnSO_4 + CuMnO_3$, and $MnMnO_3 + FeSO_4$ give $MnSO_4 + FeMnO_3$. (This latter is a very unstable body, which soon undergoes spontaneous change; but that it is formed and exists for some time I believe to be certain). Moreover, compounds in which the basic Mn of $MnMnO_3$ is replaced by other metals can be formed, not only by the reaction of $MnMnO_3$ itself upon the salts of other metals, but also by the direct reaction of nascent manganous acid upon protoxides of other metals. For example, as I stated last year, whereas if protoxide of manganese by itself be treated with air in the wet way, only one-half of it undergoes peroxidation, the other half being apparently required to furnish base to the half which becomes peroxidised, if a mixture of protoxide of manganese and an equivalent of lime be treated with air in the wet way, the whole of the protoxide undergoes peroxidation, and the lime ceases to be capable of either reacting on chloride of manganese, or of dissolving in solution of chloride of calcium. Similarly, if protoxide of manganese, suspended in solution of either baryta, strontia, soda, or potash, be treated with air, baryta, strontia, soda, or potash go out of solution, and there is formed an insoluble compound containing one equivalent of manganese, three equivalents of oxygen, and one equivalent of barium, strontium, sodium, or potassium, as the case may be.

With the existence and modes of formation of normal manganites of all these metals we were acquainted last year; what is new is the apparent formation, under the conditions of working on the large scale at which we have arrived recently, of acid manganites, or double manganites of metal and hydrogen. By far the greater number of batches containing less than an equivalent of base which have been made as yet resemble in constitution one or the other of the two representative batches, the composition of which is stated on one of the diagrams I exhibit. In one of the batches, of the total manganese operated upon 86.5 per cent had been peroxidised, and for each equivalent of peroxidised manganese present there were 0.85 equivalents of bases. Regarding the constituents of the batch, for convenience, as MnO_2 , MnO , and CaO , and considering the total manganese present as a thousand equivalents, there were thus in this batch 86.5 equivalents of MnO_2 , 135 equivalents of MnO , and 0.85 times 86.5, or 73.5 equivalent of total bases, 135 of which were MnO , the remaining 600 being CaO . Assuming that the 600 CaO were combined with 600 MnO_2 , as normal manganite of calcium, there remained 265 equivalents MnO_2 and 135 equivalents of MnO , the proportion of the former to that of the latter being very nearly two to one. These figures I hold to show the existence in this batch of an acid manganite, $MnH_2(MnO_3)_2$, or a compound containing the elements of one of normal manganite of manganese and one of manganite of hydrogen. In the other batch, of the total manganese present 81.5 per cent had been peroxidised, and for each equivalent of peroxide present there were 0.885 equivalents of bases. This batch, therefore, contained 81.5 equivalents of MnO_2 , 185 equivalents of MnO , and 536 equivalents of CaO . Assuming, as before, that all the lime existed as $CaMnO_3$, there were left 279 MnO_2 and 185 MnO . This is almost exactly three of the former to two of the latter, suggesting the existence in that batch of a sesquimanganite of manganese, containing the elements of two of normal manganite of manganese with those of one of manganite of hydrogen. In these batches, it is only acid manganites of manganese that I suppose to have existed; but one or two batches have been made, containing not much more than 0.5 equivalents of base, in which I believe that there must also have been an acid manganite of calcium. It may be, of course, that in all batches containing less than an equivalent of base a

portion of the manganous acid exists in the free state; but I have not yet met with any instance of a batch, the blowing of which I have known to have been continued until peroxidation had really ceased, and the proportion of base in which, while less than an equivalent, was such that the batch could not have consisted entirely of acid manganites, in which the peroxide remaining after deduction of the quantity equivalent to the combined lime contained in the batch was in any other proportion to the basic manganese contained in the batch than either that of two equivalents to one or that of three equivalents to two—a fact almost irresistibly suggestive of the two bodies being combined. The circumstance, moreover, that under no known conditions can peroxide of manganese be formed, by treating protoxide with air in the wet way, without some portion either of manganese itself or of some other metal going simultaneously into combination as base, strongly indicates that only salts of manganous acid can be formed in that way.

The quantity of air which requires to be blown into the oxidiser per given quantity of peroxide of manganese made varies with a considerable number of conditions, but more especially with the depth of the charge operated upon, and with the quantity of manganese contained in a given volume of it. Within all practicable limits, increase of the depth of the column blown into is equivalent to increase of the quantity of air blown; and the more particles of protoxide are contained in a given volume of the charge, the larger is the total surface which they present for the air to act upon, and the greater is the proportion of the total oxygen injected which becomes absorbed. The proportion of the oxygen absorbed to the quantity blown in being of course greatest at the commencement of the operation and afterwards continually diminishing, a time at length arriving, if the blowing be continued long enough, at which no more oxygen is absorbed at all, the proportion of the total quantity of oxygen absorbed to the total quantity blown in is also considerably influenced by how nearly to that point the operation be continued. The table accompanying shows the progress of the oxidation of three batches, made at different works, and constituting fair average examples of what takes place under the different conditions under which these three batches were respectively made. The quantities of air given are not absolutely accurate, but are very near approximations to the actual quantities. One of these three batches contained 1987 pounds of peroxide, reckoned as MnO_2 , which was made in four hours, by the injection of about 240,000 cubic feet of air, being at the rate of about 120 cubic feet of air for every pound of MnO_2 made.

This batch absorbed in the first hour 12.8 per cent of the oxygen injected, in the second hour 10.5 per cent, in the third hour 8.9 per cent, and in the fourth hour 2.0 per cent; the proportion of the total quantity absorbed to the total quantity injected being 8.5 per cent. The weight of the total oxygen absorbed was 364 pounds, of which 136 pounds were absorbed in the first hour, 111 in the second hour, 95 in the third hour, and 22 in the fourth hour. In the case of the batch next represented, a deeper column was blown into, and the blowing was stopped before the peroxidation had quite ceased. This batch contained 2500 pounds of MnO_2 , made in five hours, during which about 175,000 cubic feet of air were blown in, so that in this batch only 70 cubic feet of air were used per pound of MnO_2 made. The proportion of oxygen absorbed in the first hour was 20.2 per cent of the quantity blown in, in the second hour 17.5 per cent, in the third hour 16.3 per cent, in the fourth hour 13.6 per cent, and in the fifth hour 6.1 per cent; the proportion of the total quantity absorbed to the total quantity blown in being 14.8 per cent. The total quantity of oxygen absorbed was 458 pounds, of which 125 were absorbed in the first hour, 108 in the second, 101 in the third, 84 in the fourth, and 40 in the fifth. In the third batch, the column was also a deep one, and the chloride of manganese

liquor commenced with was unusually strong. On the other hand, however, the blowing was continued until the peroxidation was quite completed. This batch was blown eight hours, during which 432,000 cubic feet of air were injected, and 5400 pounds of MnO_2 made, being one pound of MnO_2 per 80 cubic feet of air, and the total oxygen absorbed being 13.3 per cent of the total quantity injected.

The mechanical power expended in the injection of the air into the oxidiser has hitherto averaged between seven and eight horse-power for one hour per 100 pounds of MnO_2 made. I believe that it is capable of being considerably diminished, but that is about what it has usually been hitherto. The quantity of chlorine contained in a ton of bleaching-powder at 37 per cent is liberated by 1020 pounds of MnO_2 , but, owing to the various losses of chlorine which occur in the manufacture of bleaching-powder, the quantity of manganite mud actually used per ton of bleaching-powder made by means of it is ordinarily the quantity containing about 1100 pounds of MnO_2 , the production of which may be said to require the expenditure of about thirty-five to forty horse-power for two hours.

The lime used in the oxidiser has hitherto been usually prepared in the same manner as the lime used in bleaching-powder chambers; that is to say, it has been slaked with as nearly as may be only an equivalent of water, and the resulting hydrate then separated into two portions by means of very fine sieves, only the portion which passes through the sieves being used. Including the portion which is sieved out, and which, although it does not go into the oxidiser, is usually charged to the process, the consumption of lime in the process, per ton of bleaching-powder made by means of it, at present averages about 14 cwt. At one work on the Tyne, however, it has been reduced to 12 cwt.; and if we get to make regularly, as I believe we shall, products containing not much more than half an equivalent of base, it will eventually be reduced everywhere to below 10 cwt.

The quantity of acid consumed per ton of bleaching-powder made by means of manganite mud varies with the degree of care with which the process is performed and with the general skill of the manufacturer, being in some cases very considerably below the average quantity consumed in making a ton of bleaching-powder by means of native manganese, while in other cases it is scarcely at all below that quantity. I believe that a ton of bleaching-powder is never made in this country, by means of native manganese, from less than the acid from 60 cwt. of salt, and only rarely from less than the acid from between 70 and 80 cwt. of salt. At least one manufacturer, however, whose mud contains, as yet, by no means a minimum of base, and who at present follows a method of treating the mud in the stills, which is not quite the most economical of acid, is consuming, per ton of bleaching-powder made by means of manganite mud, only 170 cubic feet of acid at 24° Twaddell—a quantity which I believe to be producible, in practice, from less than 48 cwt. of salt. As what one manufacturer is doing can surely be done by all, when equally familiar with the process, I venture to believe that a very considerable economy of acid will eventually be realised by the process everywhere.

The loss of manganese which occurs in the process at present varies from about 4 per cent to about 10 per cent. The only unavoidable source of loss is that constituted by the deposit of sulphate of lime and other matters which forms in chloride of manganese settlers. These deposited matters have to be removed in the state of thin mud, largely mixed, that is to say, with solution of chloride of manganese. Unless this mud be well washed after its removal from the chloride of manganese settlers, and the washings be returned to the process, the manganese lost with this mud amounts to fully 5 per cent, or even more; but by suitable washing the manganese thrown away with the mud from chloride of manganese settlers can be reduced to below 2 per cent. The only other sources of

loss are, leakage of vessels, and the running away of mud by careless workmen with the chloride of calcium solution from the mud-settlers. The former of these sources of loss ought, practically, never to exist, and the latter is now being eliminated at several works by the chloride of calcium solution, instead of being run away directly from the mud-settler, being run first into catch-pools, in which any mud which may be run off with it from the mud-settlers is allowed to deposit.

Beyond the sulphate of lime and other bodies which are deposited in the chloride of manganese settlers, the only residual product of the process, and the only other thing which has to be thrown away, is solution of chloride of calcium. As this solution represents all the lime and all the limestone used in the process, and two-thirds of the chlorine contained in the acid employed, and as an industrial process is, of course, imperfect in proportion as anything whatever which is manipulated in it has to be simply thrown away, and especially in proportion as its yield of the commodity, the production of which is its sole object, falls below the total quantity contained in the materials used, I have tried to use, in the oxidiser, magnesia instead of lime, afterwards decomposing, by heat, the resulting chloride of magnesium into magnesia, for use over again, and hydrochloric acid. In that form, the process is capable of yielding, undiluted with other gases, all the chlorine contained in the acid employed, and, apart from mechanical loss, employs no materials which are not used over and over again, excepting coal and air. This form of the process has already stood the test of a certain amount of experience on the large scale; and I venture to believe that, when the time shall have arrived when it will be desirable to obtain, from a given quantity of hydrochloric acid, more chlorine than can be obtained therefrom by means of peroxide of manganese recovered by means of lime, peroxide of manganese recovered by means of magnesia will prove to be the reagent by which chlorine can be most economically manufactured.

ON THE UTILISATION OF SEWAGE,

WITH SPECIAL REFERENCE TO THE PHOSPHATE PROCESS.*

By DAVID FORBES, F.R.S., &c.

SINCE the universal adoption, in this country, of water as a medium for carrying off the excreta in towns, the difficulties of dealing with the sewage question, so important from a sanitary point of view, have been immensely increased, as, instead of as formerly, having to do with but a comparatively small amount of the original matter, we have to deal with this amount diluted to several hundred times its original volume, with, at the same time (at least in most cases), a proportionately still greater decrease in its agricultural value, owing to the admixture of the waste products of other manufactures, which, in themselves, being treated with air, are less, but frequently even highly injurious to the soil, except what is carried off by evaporation, as well as what is added in order to precipitate the sewage, ultimately, by gravitation, find its way to the sea, or sink into the ground to the detriment of springs around; and, since there is no remedy but to look this difficulty in the face, and attempt to overcome it by devising some method (for I feel confident that such a method will be found) by which the sewage may be rendered innocuous, and advantageous or applicable to agricultural purposes, the ordinary reaction of an acid with an alkali, as at present, that which is ordinarily called a "phosphate process," of danger, to the soil, is really manganite of hydrogen in which

All the systems hitherto employed for this purpose may be classed under two heads—the purely Mechanical and the Mechanico-Chemical. Under the first, the sewage (lifted, by pumping, to a higher level when necessary) is allowed to flow directly into the nearest river or sea, to destroy the fish, pollute the stream, and carry the germs of disease to everywhere to which such contaminated water can penetrate; the only improvement in later times being, that at some places, the sewage is allowed, first, to settle, and deposit the larger portion of its solid contents, or, is passed through some species of filter, which, acting merely mechanically, keeps back the suspended particles.

Although sewage-water, so filtered, may appear perfectly clear to the eye, it hardly requires chemical analysis to show that it has not, in reality, been purified to any extent; the foetid smell which it emits, or which is soon developed upon standing, indicates that much organic matter capable of entering into putrefaction still remains in solution; and, although such putrefaction may, in some degree, be counteracted or retarded by the use of disinfectants or antiseptics (like carbolic acid, &c.), still I think it is now generally acknowledged that the required putrefaction cannot be effected by any merely mechanical system whatever.

Coming now to the mechanico-chemical systems proposed for the utilisation of sewage, we must class sewage irrigation under this head, not because it involves (at least, as usually carried out) any direct chemical treatment of the sewage, but because this system is based upon a combination of purely mechanical filtration, the soil acting as a filter, with the chemical action brought into play by the growth of the vegetation, which decomposes and assimilates the organic matter and other available substances, both in the liquid, as well as in the solid matter of the sewage; and, provided the proper ratio be observed between the supply of sewage to the ground and the capabilities of the crops to assimilate its contents, the surplus water will drain from the land in a comparatively pure and innocuous condition; so that this system, which might be appropriately termed the natural system of sewage irrigation, if properly carried out, utilises at once both the entire liquid as well as solid contents of the sewage, and leaves nothing more to be desired, provided only that the local circumstances are favourable to its being carried out.

It must not, however, be supposed to be without its drawbacks, and there are also numerous localities where sewage irrigation does not appear to be either applicable or advantageous.

It must be remembered that the distribution of foetid sewage water must taint the surrounding air; and when the soil does not allow the sewage to sink quickly into its substance or, especially if stiff clay or not well drained, becomes saturated with sewage, the smell may become so offensive that the neighbourhood will not submit to it; and it is no wonder that, under such circumstances, evidence has already been brought forward to prove that (for example, at Croydon) contagious fevers are either generated or become more prevalent. It is also stated that sewage irrigation is not suited for all crops, although very advantageous for some—as, for example, Italian rye-grass; so it becomes a question, also, as to whether a sufficient sale can be obtained for such crops in the neighbourhood; and in the case of one sewage-farm last year, I am informed that this was not the case. As far as present experience goes, it indicates also that the continued use of sewage over the same land ultimately tends to produce an unhealthy condition of vegetation; and certainly it appears to have been proved that a limit is soon reached beyond which the application of more sewage may even be positively injurious.

The expense for machinery, and appliances for pumping and distributing the sewage, of many large towns, especially when the sewage cannot be all brought to one centre, must often be so great as to deter companies, or even municipalities, from adopting this system; and, in many cases,

suitable land cannot be obtained at all, or only at such great distances as to still further augment this great outlay. Besides this, it must be borne in mind that the area of land required to assimilate the whole of the sewage of a town like London, or any of our great commercial centres, without becoming supersaturated, will be both extremely large, as well as costly; since the value of land in the immediate neighbourhood of large towns is, as a rule, not dependent upon the value of the crops it will furnish, but is of a fictitious but infinitely higher value for building sites, &c. As regards the area required for sewage cultivation, I was informed, on a recent visit to the sewage farm at Warwick, that, after a three years' trial of 100 acres, it was found that double this amount of land would be required, in order to fully utilise the entire sewage. Now, as Warwick has only 10,000 inhabitants, and is particularly favoured by being a strictly rural town, without any chemical or other manufactory, it would follow, at this rate, that it would require much more than 60,000 acres to absorb the sewage of London.

Fully admitting the advantages of sewage irrigation when applied in certain localities, I still believe that, taking all the above circumstances into due consideration, you will agree with me as to the importance of searching for some chemical process by which the sewage may be deodorised and purified at once—at least, to such an extent, that the supernatant water may be directly run off into the rivers or sea—without danger to health or animal life, and thus avoid the necessity of erecting costly works for the collection and transmission of the sewage to localities miles distant, where it is distributed to taint the surrounding atmosphere.

Many attempts have, as might have been expected, been already made in this direction. As early as 1845, works were erected in Edinburgh, to which I acted as chemical adviser in which the sewage was treated with lime, a process which, in later years, has been carried out at Leicester, Tottenham, and Blackburn, but which has proved a failure, in a sanitary point of view, because it did not effect a sufficient purification of the water; and, as a commercial speculation, because the precipitate or manure obtained was comparatively worthless, being actually of less value than the original deposit from the sewage itself.

The treatment of sewage with lime and chloride of iron, as used at Northampton, is a process which, although apparently an improvement upon the treatment by lime alone (at least, in so far as regards the purification of the affluent water), has also failed as a commercial success, for the same reasons.

It has been known from very ancient times, that alum has a remarkable decolourising and purifying influence on foul water, which appears to be due to the property which alumina and certain other compounds have of forming combinations with organic matter and producing compounds more or less insoluble in water, a property which has long been utilised in the arts of dyeing, the manufacture of pigments and sugar, the clarification of liquids, &c., and which of late years has been applied to the purification of sewage, the salts used being ordinary alum and crude sulphate of alumina. The purification of sewage-water so effected is, however, not considered by the Rivers' Pollution Commission to be sufficient; and the value of the precipitated deposit, when used as manure, is but little better than the mere deposit from the sewage itself.

The so-called A B C process, which has of late been prominently placed before the public in connection with the Leamington and Hastings sewage, is carried out by adding to the sewage an extraordinary mixture of clay, along with alum, blood, animal or vegetable charcoal—burnt clay, salt, magnesian limestone, and compounds of magnesia and manganese, the last five substances, if not necessary, being omitted.

The major part of the purifying mixture is the clay, and next in quantity the alum, all the other substances

being added in so insignificant a proportion that they can hardly be expected to influence the result in any great degree. The chemical action of the alum has been already alluded to; but the clay seems to play a mere mechanical part, by entangling the suspended matters in the sewage, and so causing them, by its weight, to sink down or transport them to the bottom of the tank more quickly. An inspection of the working of the process at Leamington made me endorse the opinion already given by the Rivers' Pollution Commission, that it altogether failed to effect any sufficient purification of the sewage-water, or to produce a manure of such commercial value as could possibly ensure its sale at a price which could pay for its carriage to any distance beyond its immediate neighbourhood.

Having now alluded to all the principal methods which have already been tried for sewage purification and utilisation for manure, I will call your attention to an entirely novel process now brought forward by Dr. Apsley Price and myself, and which we have called the phosphate process.

This process is founded on the fact that certain mineral phosphates, easily obtainable, especially those containing alumina, when in a hydrated or freshly-precipitated state, eagerly combine with the organic matter contained in the sewage, it being sufficient merely to agitate them in the most fetid sewage to deprive it of all its odour and colour, even if tinctorial substances of great intensity be present in the solution at the same time; whilst the phosphate of magnesia combines with the ammonia contained in the sewage, and precipitates it also in the state of the double phosphate of ammonia and magnesia.

The precipitate subsides rapidly, and the water drawn off is, as you see in the experiments here before us, quite transparent, colourless, and has so little perceptible taste, that you can drink it without repugnance if you can only banish the idea from your minds that it has only just been obtained from so filthy a source.

The process is, as you will see, an extremely simple one, and requires nothing beyond a reservoir for holding the sewage whilst it is submitted to the operation. The phosphates are preferably added, in the state of solution, in sulphuric or hydrochloric acid, to the sewage, and their precipitation, in the hydrated form, along with the organic matter in the sewage, and more or less of the ammonia (dependent on the strength of the sewage and amount of time allowed to stand), is instantaneously effected by the addition of a small quantity of milk of lime, just sufficient to neutralise the acid which holds them in solution, the deposit subsides rapidly, and the supernatant water may at once be run off and discharged into the river.

Before recommending this process for adoption, we must necessarily be prepared to answer two questions, as to—

(1) Whether the water discharged after this treatment is sufficiently pure to be permitted to flow into the rivers? And—

(2) Whether the valuable constituents of the sewage have been precipitated?

Before answering the first of these questions, another must be asked, which is—When can such water be regarded as sufficiently pure? and on this point opinions are much divided; some demanding a standard of purity as high, or even higher than many natural drinking waters, whilst others are content when the affluent water is colourless, clear, and devoid of offensive smell. As the old saying is, whilst the doctors differ the patient dies, so, in this case, we still find the most offensive sewage allowed to run into and pollute our streams, because the present processes, although certainly better than no treatment at all, have not as yet secured such an ideal standard of perfection as, practically, they are not even likely ever to attain.

As regards the phosphate process, we do not claim that the affluent process is by anything like as pure as the

water supplied for drinking purposes, but are content with showing that it is as transparent and colourless as ordinary river water: that it can be taken into the mouth, and even drunk, without repugnance; that fishes can live in it; and, most important of all, that it is not only free from any offensive smell, but, as in the specimen on the table before you, has remained for months, during the entire hot summer of this year, without showing any tendency to putrefy or emit any disagreeable odour. So that, for the above reasons, we believe that the affluent water from the phosphate process may be allowed to flow directly into the rivers, without injury either to the fish in them or the health of the inhabitants on their banks.

Coming now to the second question, I would premise by stating that I believe that the agricultural value of sewage has, in general, been much over-estimated. That the excreta may have originally represented a value of from eight to twenty shillings per head, as estimated by various writers, is not improbable; but it is as incorrect to regard the sewage as representing the same value as the original excreta as, for example, to assert that the water in a barrel into which a bottle of brandy worth 5s. had been poured as equal in value to the original brandy; and I imagine that the most inveterate toper would decline to drink off the barrel for the sake of utilising the brandy in it. The whole of the brandy could be recovered by distillation, but probably at a cost greater than its value; and this would also be the case with sewage if we attempt to extract the entire manurial contents.

Chemists are all agreed that no chemical combinations are known by which the whole of the sewage contents valuable for agriculture can be precipitated; and in our attempts, fully recognising this, we have only endeavoured to extract so much as will leave the affluent water in a condition sufficiently pure as to be innocuous. In regard to the ammonia, the phosphate process converts it into the most insoluble compound known, the double phosphate of magnesia and ammonia, and the extent to which it is recovered is dependent upon the length of time allowed for subsidence and the solvent action of the water, whilst, as before stated, the experiments already made with London sewage from Barking Creek shows that the purified sewage retains but a mere trace of organic matter.

A most important feature of the phosphate process, however—one in which it differs from all those already described—is the fact that the substances employed in the purification are only such as really augment greatly the agricultural value of the precipitated manure, and thus make it sufficiently valuable to bear the cost of transport to a distance.

The solid deposit from sewage, when considered as a manure, is admitted to be but of extremely little value; so that if, as in the A B C and other processes, a large amount of clay, or other equally worthless substance, is added, this small value per ton is diminished to an extent that the resulting manure becomes utterly worthless, except in the immediate vicinity of the works. On the other hand, by the new process, what is added are compounds rich in phosphoric acid, in a state of combination available for immediate assimilation by the plants themselves.

The natural phosphate of alumina, which we specially recommend, is a product which at present has no commercial value, and occurs in the West Indian Islands in such enormous quantities that, on one island alone, the report of the survey estimates the deposit at no less than 9,000,000 tons. Many other natural phosphatic deposits, found both in this country and elsewhere, are also capable of furnishing an abundant supply of material well suited for carrying out this process at but a very small expense.

In conclusion, I may state that the object in bringing forward this communication is to direct attention to a process which, we believe, may prove an extremely valuable one in such localities as are found unsuitable for sewage irrigation, for some of the reasons before stated.

ON THE SO-CALLED "ALKALINITY OF CARBONATE OF LIME."

By CHARLES R. C. TICHBORNE, F.C.S., M.R.I.A., &c.

My attention has been drawn to a paper by Mr. Skey, in which he states that carbonate of calcium, either artificially prepared, or in the form of limestone or calc-spar, possessed well-marked and rather decided alkalinity.* I have been experimenting lately with lime and its compounds, and as that statement was so contrary to my observations, I think it well to point out wherein, in my opinion, lies Mr. Skey's error (a very natural one). Such statements frequently creep into manuals and other works on chemistry without being submitted to sufficient proof, and become accepted as facts.

It will be observed on reading Mr. Skey's communication that he simply relies on reddened litmus paper as a proof of the alkalinity. Now, if we examine the condition of red litmus paper, we see at once that the tinctural matter is simply loosely combined with the acid used to redden it, and that the carbonate of calcium acts by abstracting the acid, and thus the litmus is brought back to its normal colour—a blue with a shade of violet.

If Mr. Skey will repeat the following experiment, I think he will be persuaded of the neutrality of carbonate of calcium.

A little water was re-distilled from a few grains of bisulphite of potassium, the object being to get a perfectly neutral water, almost all distilled water being faintly alkaline. Red litmus paper was made by moistening litmus paper with very dilute acetic acid, washing, and drying. Blue litmus paper was purified by washing with pure water, by which it generally becomes a little more violet, the blue of ordinary litmus being due to a slight alkalinity; turmeric paper was also washed. The three papers, as thus prepared, were then placed into a test-tube with the above water, and a few grains of pure precipitated carbonate of calcium, which I had by me from a previous experiment, was added. The red litmus speedily became of its normal shade, from the abstraction of the acetic acid to form the acetate of calcium, but, on standing twenty-four hours, the other two papers did not show the slightest sign of alkalinity; even blue litmus, under such a circumstance, would become a most delicate test, as it becomes distinctly bluer to an experienced eye, and such was not the case.

The experiment was repeated, but in this case a rhomb of Iceland spar was coarsely crushed and used as the carbonate; exactly similar results were obtained, except that the change in the red litmus was slower and evidently took place only where the particles of spar were in actual contact. The blueing of the litmus paper proceeded in blotches; there was no change with the blue litmus or the turmeric papers.

Carbonate of calcium is quite neutral, and it is evident that reddened litmus paper is not reliable as a test in such a case as the above.

Laboratory, Apothecaries' Hall of Ireland.
September, 1870.

ON THE PRECIPITATION OF CÆSIUM AND RUBIDIUM SALTS WITH THE INSOLUBLE SALTS OF LIME.

By J. LAWRENCE, SMITH.

HAVING seen E. Sonstadt's statement in the July number of the *CHEMICAL NEWS*, and having worked a great deal with the salts referred to in connection with lime, I never observed the reactions alluded to in Sonstadt's paper. If true, they would effect very materially the

* *CHEMICAL NEWS*, vol. xxii., p. 85.

results of certain analyses in which I am now engaged; some special investigations were, however, made, to test the accuracy of his statements. 500 m.g. of pure carbonate of lime were dissolved in hydrochloric acid with 20 grammes of water; to this 150 m.g. of chloride of cæsium were added; the lime was now precipitated by carbonate of soda, the precipitate thrown on a filter and washed with the usual precautions adopted in all my analyses; the carbonate dried and weighed gave 499 m.g. of carbonate of lime.

The same experiment was made substituting carbonate of ammonia for the carbonate of soda, and the resulting carbonate of lime was 498 m.g.; the filtrate was evaporated to dryness and ignited gently, to drive off sal-ammoniac; the residue was 151 m.g., having used 150 m.g. of chloride cæsium. An experiment was also made using oxalate of ammonia; the resulting carbonate was with $\frac{1}{4}$ m.g. of the carbonate of lime originally used. Still another experiment was made, identical with the first, and the resulting carbonate of lime was within $\frac{1}{4}$ m.g. of the original quantity.

Experiments were made with lime and the rubidium salts, with similar results; so that Sonstadt must be mistaken in the precipitation of rubidium and cæsium salts, when lime is thrown down in the form of carbonate from solutions containing both lime and rubidium and cæsium salts, or I must have made my experiments under very different conditions from those made by him.

Louisville, Ky., August 11th, 1870.

[Professor Smith will find, on reference to our issue of July 22, that Mr. Sonstadt has anticipated the corrections which he (Professor Smith) makes.—*Ed. C. N.*]

PROCEEDINGS OF SOCIETIES.

ROYAL INSTITUTION OF GREAT BRITAIN.

Notes of a Course of Seven Lectures on Electrical Phenomena and Theories. By Professor TYNDALL, LL.D., F.R.S.

(Concluded from p. 115.)

Influence of Time on Intensity of Discharge. The Condenser.

315. The intensity of the secondary current—its "discharging distance," for example—depends upon the rapidity with which the primary is interrupted.

316. I have already referred to the passage of particles between the two severed terminals of a circuit. By these particles the current may be kept up for a short time after the terminals have been disunited. A gradual dying away of the primary is the consequence.

317. But to produce the maximum secondary intensity it is necessary that the primary should be extinguished at once.

318. This is very effectually accomplished if the primary be broken between the poles of a strong magnet. The secondary spark may be thus made to overleap distances, vast in comparison with those possible to it when the rupture of contact occurs far away from the magnetic poles.

319. The magnet quenches immediately the stream of particles which accompany the spark. Thus, instead of being spread over a very sensible interval, the whole power of the primary is concentrated into an instant of time.

320. This concentration is announced by the loudness of the report of the primary spark. This augmentation of loudness was first observed by Page; it was explained by Rijke, who also exalted in the way here indicated the discharge of the secondary coil.

321. The injurious effect of the spark produced by the

rupture of contact in Ruhmkorff's coil is much diminished by the employment of a condenser, which is attached to the primary. It was introduced by Fizeau.

Electric Discharge through Rarefied Gases and Vapours.

322. The electricity from the prime conductor of an electrical machine passes through the air in the form of a dense and brilliant spark, which produces a very audible report.

323. When the discharges pass through rarefied air the discharging distance is augmented, and by sufficiently rarefying the air the discharge may be caused to pass silently. It then fills the tube through which it passes with a rosy light.

324. This rosy light has the same origin as that of the Aurora Borealis: it is due to the nitrogen of the air.

325. Every attenuated gas has its own characteristic colour when traversed by the electric discharge. When examined by a prism, the colour resolves itself into distinct bands; the nature of the gas may indeed be inferred from the analysis of its spectrum.

326. The discharge of the induction coil through attenuated media produces luminous effects similar to those produced by the electric machine.

327. The tubes containing the attenuated gases or vapours are usually called *vacuum tubes*. Through the tubes pass platinum wires which are fused into the glass, and between which the discharge passes.

328. Such tubes are produced in great perfection by Geissler, of Bonn, and are sometimes called Geissler's tubes.

329. Under certain circumstances, the luminous discharge is composed of distinct luminous strata, separated from each other by dark intervals transverse to the direction of the discharge. These strata were first observed by Grove; they were first observed independently and finely developed by Ruhmkorff.

330. The luminous strata were believed to arise from the intermittent action of the contact-breaker of the induction coil; but Gassiot produced them both with the electric machine, and with his battery of 3500 cells, where no contact-breaker is employed.

331. Every single discharge of the induction coil through a properly chosen medium resolves itself into a series of pulses, which declare themselves as a stratified discharge. Under similar circumstances the discharge from the voltaic battery also is resolved into a series of pulses which are declared by their stratifications.

Action of Magnets on the Luminous Discharge.

332. The luminous discharge is, to all intents and purposes, an electric current, and is acted on by a magnet like a wire carrying a current.

333. But the flexibility of the luminous current in rarefied gases enables the magnet to act upon it in a manner peculiarly interesting and instructive.

334. Placing, for example, a tube through which the luminous discharge is passing between the poles of an electro-magnet, by exciting the magnet the stream of light may be either deflected or wholly extinguished.

335. In the latter case, by interrupting the current passing round the magnet, or by lifting the tube out of the magnetic field, the luminous discharge is restored.

336. In certain cases, when the luminous discharge consists simply of a feeble glow, the supervention of the magnetic force draws a series of strongly illuminated strata from the positive terminal of the vacuum tube; when the magnetism is interrupted, these strata retreat again in succession, as if swallowed up by the positive pole. A number of exceedingly beautiful experiments of this character has been made by Gassiot.

337. It has been stated in Note 306 that the discharges from the induction coil proceed always in the same direction; hence in each vacuum tube we have a positive terminal or pole, and a negative terminal or pole.

338. When the light surrounding the negative terminal

is subjected to a magnet, it ranges itself exactly along the lines of magnetic force; the light at the positive terminal shows no such action. This discovery is due to Plücker.

Magneto-electric Machines. Saxton's Machine. Siemens's Armature.

339. Faraday's discovery of magneto-electricity was announced in 1831. In 1833 a machine was constructed by Saxton for the more copious development of magneto-electric currents.

340. In it copper-wire coils, within which were placed cores of iron, were caused to rotate before the poles of a powerful magnet.

341. On the approach of a coil to one of the poles of the magnet, a powerful current, whose direction depended on the nature of the pole, was induced in the coil. When the coil retreated from the magnetic pole, a current in the opposite direction was induced. This production of opposite currents by approach and withdrawal has been already referred to in Notes 283, 284.

342. By means of an instrument called a *commutator*, which reversed one of the induced currents at the proper moment, the opposite currents were caused to flow in the same direction.

343. The cores of soft iron and their associated coils constitute what is called an *armature*. In Saxton's armature the coils were wound *transversely* to the iron cores.

344. But, by winding his coils *longitudinally*, or parallel to the axis of the core, and placing the armature so formed between the poles of a series of horse-shoe magnets, Siemens obtained magneto-electric currents much more powerful than those of Saxton.

Wilde's Machine.

Things were in this state when, in 1866, Wilde made an important addition to our knowledge of magneto-electricity.

345. He conducted the current obtained by means of Siemens's armature round an electro-magnet, and found that the magnetism thus excited was far greater than that of the entire series of steel magnets employed to generate the magneto-electric current.

346. Thus, in one case, he found that, whereas the series of permanent magnets taken collectively was competent to support a weight of 40 lbs. only, the electro-magnet which they excited sustained a weight of 1088 lbs.

347. To produce this effect, however, it was necessary that the armature of the magneto-electric machine should rotate with great rapidity.

348. But Wilde went farther. Forming his electro-magnet from a large plate of iron, and placing between its long poles a correspondingly long armature, similar in shape and construction to that of the magneto-electric machine, he obtained from this second armature currents of enormously greater power than those obtainable from the first.

349. These currents could, in their turn, be sent round a second electro-magnet, formed from a larger plate of iron. Furnished with a rotating armature, this second electro-magnet produced effects previously unknown. Rods of iron a quarter of an inch in thickness were fused by the currents, and they were also found competent, when discharged between carbon terminals, to produce a light of intolerable brilliancy.

Siemens's and Wheatstone's Machine.

350. The next great step in magneto-electricity was made simultaneously by Dr. Werner Siemens and Sir Charles Wheatstone.

351. Expressed generally, this discovery consists in exalting, by means of its own action, to a high pitch of intensity an infinitesimal amount of magnetism.

352. Conceive an electro-magnetic core with a very small amount of residual magnetism, which is never

wholly absent when iron has been once magnetised. Let a secondary coil, with cores of soft iron, rotate before the poles of such a magnet. Exceedingly feeble induced currents will circulate in the secondary coil. Let these induced currents, instead of being carried away, be sent round the electro-magnet which produced them; its magnetism will be thereby exalted. It is then in a condition to produce still stronger currents. These also being sent round the magnet, raise its magnetism still higher, a more copious production of induced currents being the consequence. Thus, by a series of interactions between the electro-magnet and the secondary helix, each in turn exalting the other, the electro-magnet is raised from a state of almost perfect neutrality to one of intense magnetisation.

353. When the magnet has been raised to this condition, other coils than those employed to magnetise it may be caused to rotate before, or between, its poles; the currents from these coils may be carried away and made use of for magnetisation, for chemical decomposition, or for the electric light.

354. The first magneto-electric machine used to produce a light sufficiently intense for lighthouses was constructed by Mr. Holmes. In it permanent steel magnets and rotating helices were employed. Mr. Holmes has lately constructed a very powerful machine on the principle of Siemens and Wheatstone.

Induced Currents of the Leyden Battery.

355. If a Leyden jar, or battery, be discharged through a primary spiral, it evokes a current in a secondary spiral. With a strong charge this secondary current may be caused to deflagrate a foot of thin platinum wire.

356. If the current from the secondary spiral be led round a third spiral which faces a fourth, on discharging the battery through the primary spiral, the secondary in the third spiral acts the part of a primary, and evokes in the fourth spiral a *tertiary current*.

357. With another pair of spirals this tertiary current can be made to generate a current of the *fourth order*; this, again, with another pair of spirals, a current of the *fifth order*. All these currents can impart shocks, ignite gunpowder, or deflagrate wires.

For the investigation of the induced currents of the Leyden battery we are indebted to Professor Joseph Henry, Director of the Smithsonian Institution, and to Professor Riess, of Berlin.

NOTICES OF BOOKS.

Researches on Diamagnetism and Magne-Crystalline Action, including the Question of Diamagnetic Polarity. By JOHN TYNDALL, LL.D., F.R.S., &c., Professor of Natural Philosophy in the Royal Institution of Great Britain. London: Longmans, Green, and Co., 1870.

THE work before us is a first instalment of the collected publication of the author's original memoirs on experimental physics, communicated by him to the *Philosophical Transactions* and the *Philosophical Magazine*, during the last 18 years. These researches were begun at Marburg at the close of 1849, and have been since continued at Berlin, and completed in England. In the introduction to this series of memoirs, the author relates the discovery of, and first researches on, diamagnetism, by the celebrated Faraday. The first 184 pages are devoted to eight memoirs by the author, and the remainder of the volume contains letters, essays, and reviews relating to magnetism and electricity; the work as it is gives to the reader a very complete and excellent account of all facts and theories relating to this portion of natural philosophy. It is copiously illustrated with plates and woodcuts, and is, in every sense of the word, a most interesting as well as useful publication.

MISCELLANEOUS.

British Association for the Advancement of Science.—The following is a complete list of the papers which were brought before Section B (Chemical Science), at the Liverpool Meeting, under the presidency of Dr. Roscoe, F.R.S. They will be published, in full or in abstract, according to their importance, in the CHEMICAL NEWS. The President's Address.

Report of the Committee on the Chemical Nature of Cast-Iron.—Communicated by D. Forbes, F.R.S.

Henry Deacon, J.P.—A New Chlorine Process without Manganese (with illustrations).

Walter Weldon.—On the Weldon Process for the Manufacture of Chlorine (with illustrations).

A. E. Fletcher, F.C.S.—Air Pollution from Chemical Works.

J. Berger Spence, F.C.S.—On the Phenomena of the Crystallisation of a Double Salt.

W. H. Perkins, F.R.S.—On Artificial Alizarine (with illustrations).

W. Gossage, J.P.—On the Lancashire Alkali Trade.

T. Fairley, F.C.S.—On the Hydrogenation and Hydriodate of Cyanogen.

T. Fairley, F.C.S.—On the Distillation of Sulphuric Acid. Dr. Hurter.—On the Time Needed for the Completion of Chemical Change.

J. H. Gladstone, F.R.S.—On Reciprocal Decomposition Viewed with Reference to Time.

A. Vernon Harcourt, F.R.S.—On a Method for the Determination of Sulphur in Coal Gas.

W. Marriott, F.C.S.—On the Estimation of Sulphur in Coal Gas.

J. Dewar, F.R.S.E.—Note on Thermal Equivalents—1. Fermentation. 2. Oxides of Chlorine.

J. Spiller, F.C.S.—On the Discrimination of Fibres in Mixed Fabrics.

Report of the Committee on the Treatment and Utilisation of Sewage.

David Forbes, F.R.S.—On the Utilisation of Sewage, with Special Reference to the Phosphate Process.

James Hargraves.—On the Separation from Iron Furnace Cinder of Phosphoric Acid for Manurial Purposes.

E. C. C. Stanford, F.C.S.—On the Retention of Nitrogen by Charcoal.

Dr. Gerland.—On the Action of Sulphurous Acid in Aqueous Solution on Phosphates and other Compounds.

A. E. Fletcher, F.C.S.—On the Purification of Sankey Brook.

R. C. Tichborne, F.C.S.—Dust as a Ferment.

E. Schunck, F.R.S.—On the Chemical Composition of Cotton.

C. Tomlinson, F.R.S.—On the Action of Low Temperatures on Supersaturated Saline Solutions.

C. Tomlinson, F.R.S.—On a Salt Invisible in its Mother Liquor.

Peter Spence, F.C.S.—On an Attempt to Determine the Boiling-Point of the Saturated Solution of Various Salts by Boiling with Steam of 100° C.

J. Birkbeck Nevins, M.D.—On a New Theory respecting the Heating of Liquids.

Professor A. W. Williamson, F.R.S.—Communication respecting a Resolution of the Committee of Section B on the Proposed Establishment of a New School of Applied Science by Government.

Professor Roscoe, F.R.S.—On Vanadium (illustrated by preparations of its compounds).

Dr. B. W. Gerland.—Note on the Occurrence of Vanadium.

J. Arthur Phillips, F.C.S.—Note on Claudet's Process for the Extraction of Silver.

W. H. Walenn, F.C.S.—On the Electrolytic Deposition of Copper and Brass.

J. Fenwick Allen, F.C.S.—On the Alloys of Copper, Tin, Zinc, and Lead with Manganese.

A. M'Gordon.—How to Prevent Lead-Poisoning in Water.

Dr. Moffat.—On Atmospheric Oxone.

E. C. C. Stanford, F.C.S.—On the Marbles of Tyree.

A. H. Church, M.A.—Experiments on the Preservation of Stone.

Rev. H. Highton.—On Artificial Stone and Certain Forms of Silica.

W. J. Cooper.—On the Use of Solutions of Soluble Chlorides for Laying Dust in Thoroughfares.

W. C. Roberts, F.C.S.—Note on the Absorption of Hydrogen by Electro-Deposited Iron.

Dr. Moffat.—On the Excretion of Phosphoric Acid in Connection with Atmospheric Conditions.

A. H. Church, M.A.—Contributions to Mineralogical Chemistry.

Place of Meeting for Next Year.—It has been decided to hold the next meeting of this Association at Edinburgh, under the presidency of Sir William Thomson, F.R.S., &c. The meeting in 1872 will be held at Brighton.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

Berichte der Deutschen Chemischen Gesellschaft zu Berlin, No. 13, 1870.

This number contains the following original papers and memoirs:—

New Methods of Water Analysis.—A. Müller.—The author of this paper proposes the concentration of water by means of partial evaporation *in vacuo*, the residue to be dialysed, and the colloidal substance to be submitted to putrefactive fermentation. The mineral residue formed by the method of concentration of the water just alluded to is also to be dialysed by the aid of the addition of some hydrochloric acid. The estimation of the various constituents of water is described as follows:—The water to be analysed is evaporated to dryness, after the addition of an excess of any alkaline carbonate; the dry residue is digested with hot water, and the solution filtered; the insoluble matters collected on the filter, consisting of the earthy substances contained in the water, and also the silica and phosphoric acid. The filtrate is first very accurately neutralised with either nitric, sulphuric, or hydrochloric acids, and evaporated to dryness, and next dried at from 115° to 120°, until no more loss by weighing is observed. The dry residue is, after having been weighed, first ignited by itself, and again after the addition of bichromate of potassa.

Homologues of Isethionic Acid.—E. Schwarz.—This lengthy memoir is divided into the following sections:—Experiments in the methyl, amyl, butyl series; sulphuric anhydride.

Rufigallic Acid.—B. Jaffé.—The author refers to the researches of Robiquet, Löwe, Malin, and others on this subject. The chief point of interest in this paper is the fact that rufigallic acid, when distilled with pulverised zinc, yields a hydrocarbon which, in every one of its reactions, exhibited properties akin to those of pure anthracene; while the author also observed that rufigallic acid is very similar, though not identical, with alizarine, in this respect, that it (rufigallic acid) dyes cotton, previously mordanted with aluminous and ferric mordants, fast, but by no means bright or brilliant colours. The formula of rufigallic acid is $C_{14}H_8O_4$, containing 40 more than alizarine. A great portion of this paper is devoted to a lengthy review of the constitution of rufigallic acid and its relation to anthracene; but this portion of the paper is illustrated by a series of lengthy and complex formulae, which space forbids us to reproduce here. The preparation of alizarine from rufigallic acid by means of reducing agents is considered by the author as possible, but he has not yet succeeded in this direction.

Elementary Analysis.—L. Carius.—The author first refers to his former communications on this subject, published some years ago in other periodicals, and next explains that his process of analysis is chiefly intended for the rapid estimation of other elements than C, H, N, and O, present in organic compounds. His plan of action consists in an oxidation of the organic bodies enclosed in sealed tubes, heated to various but high temperatures, the glass tubes being enclosed in iron tubes. The oxidising agent chiefly employed is pure nitric acid; and the author states that this body can be heated by itself, without very much dissociation, to about 250°. It is clear, however, that, for the purpose herein alluded to,

the glass tubes should be strong, and their dimensions comparatively narrow, since, even with such small quantities as only 2.1 to 4.2 grams of nitric acid, in tubes of from 45 to 50 c.c., the internal pressure may range from 22.3 to 41.6 atmospheres (each atmosphere = 15 lbs. to the square inch). The author states that, even if the temperature were raised to from 320° to 350°, no explosion took place. The paper, illustrated with a woodcut, gives a lengthy description of the mode of operation; and some instances are quoted to prove the value and ready action of this method. Charcoal disappears entirely at 250°; graphite requires, from 300° to 330° for complete oxidation in two hours. The quantity of organic matter to be operated upon may be small, 1 grm. of material answering the purpose completely.

Vapour Density of Acetic Acid.—A. Naumann.—The author draws the undermentioned conclusions from some 70 vapour density estimations, made at varying temperatures and pressure:—(1) When the temperature remains constantly the same, the quantities of acetic acid contained in the unit of volume increase in greater ratio than does the pressure. (2) The density of the vapour of acetic acid, compared with that of air, under the same conditions of pressure and temperature, decreases with an increase of temperature, even though the quantity of vapour remains the same. Hence it follows that (3) the vapour of acetic acid, at different temperatures, cannot be composed of mutually-similar molecules; but equal quantities of acetic acid form, at lower temperatures, a smaller number of molecules. (4) Presumably, when an average distance between the molecules has been reached, the attraction of the molecules decreases.

On Benzo-Kreatine.—P. Griess.—This paper is chiefly a collection of lengthy and complex formulae. Benzo-kreatine is the name given by the author to a new base, derived from amido-benzoic acid cyanide. The formula of benzo-kreatine is $C_{10}H_{10}N_4O_6$. Benzo-kreatine stands in the same relation to amido-benzoic acid as kreatine does to sarkosine.

Researches on the Ether-Derivatives of Poly-Atomic Alcohols and Acids.—L. Henry.—This very lengthy memoir is divided into the following sections:—Action of pentachloride and pentabromide of phosphorus upon some ethers; glycolic acid ether and lactic acid ether (the latter is the paraffinic acid ether, as stated in a footnote); malic acid and uvic acid diethyl ether.

Preparation of Napthoe Acid on the Large Scale.—V. Merz and H. Mühlhuser.—This paper is identical with that quoted by us from No. 13 of the *Zeitschrift für Chemie von Beilstein*.

On Curcumine.—J. Kachler.—The author's researches on this subject were begun before those of MM. Daube and Gajewsky (see *CHEMICAL NEWS*, vol. xxi., p. 84) on this subject were published. As regards the contents of this paper, we learn, in the first place, that an aqueous decoction of the previously-ground root is a yellow-coloured turbid liquid, which can only be obtained free from vegetable matter insoluble in water by being passed through a silk sieve. The decoction contains, in addition to the ordinary vegetable substances, a large quantity of acid oxalate of potassa. The residue of the root, having been dried, was first treated with sulphide of carbon, yielding to it about 8 per cent of dark red coloured, fixed, fatty, very difficultly-saponifiable oil, which, when treated with sodium amalgam is decolourised so far as to become straw-yellow coloured; it consists of 79.8 per cent of carbon and 9.6 per cent of hydrogen, the remainder being oxygen. After having been treated with sulphide of carbon, and dried, the residual matter of the turmeric was exhausted with concentrated alcohol, yielding to it a dark brown-red coloured resin, which was found to be partly soluble in ether, and constituting what has been named curcumine. The author purified this resinous body, by dissolving it in dilute ammonia, precipitating that solution with chloride of calcium, collecting on a filter what was thrown down, and obtaining, by adding to the yellow-coloured filtrate, some hydrochloric acid, a yellow flocculent substance, which, after having been thoroughly well washed, was dried *in vacuo* over sulphuric acid, and constituted a chrome-yellow coloured powder, which, on elementary analysis, yielded, in 100 parts:—Carbon, 69.90; hydrogen, 5.70. The author's opinion is that this body may be simply chrysophanic acid; and he tested this experimentally by distilling a small portion with pulverised zinc, obtaining thereby, as far as the tests executed upon a small quantity admitted of ascertaining it, a body identical with anthracene. Raw curcumine, as first obtained by exhaustion of the turmeric with alcohol as above mentioned, was dissolved in warm and very dilute caustic potassa; the deep red-brown coloured solution was boiled with sodium amalgam, and thus decolourised to a light yellow colouration. Access of air being sedulously avoided, the alkaline fluid was precipitated with an acid yielding a buff-coloured, flocculent, resinous precipitate, *a*; the filtrate containing a substance, *b*, which was extracted from the liquid with ether. *a* is evidently a resin readily soluble in alcohol, but difficultly in ether, benzol, and sulphide of carbon; after having been dissolved in alcohol, and precipitated again with water, and dried, it was found, on elementary analysis, to contain, in 100 parts:—Carbon, 73.77; hydrogen, 7.76. On being oxidised with fusing caustic potassa, it yields protocatechic acid. As regards *b*, it was left, after evaporation of the ether, as a syrupy body, consisting chiefly of a weak acid which combined well with bases; but the author's researches in this direction are not complete, for want of sufficient material, and are to be resumed.

Researches on the Specific Heat of the Aqueous Solutions of Chemical Compounds.—J. Thomsen.—This very lengthy memoir contains chiefly the following series of tabulated forms and results of experiments:—Specific heat of sulphuric, nitric, hydrochloric, and tartaric acids at 18°; molecular caloric of solutions of sulphuric, nitric, hydrochloric, and tartaric acids; specific heat of the alkalis—viz., hydrates of potassium and sodium, and hydrate of ammonium, at 18°; molecular caloric of aqueous solutions of caustic potassa, soda, and ammonium-hydrate.

Cyan-Benzidine.—E. Wittenstein.—Benzidine, prepared from azobenzol, was dissolved in alcohol, and into this solution cyanogen gas was passed until supersaturated with that gas. This alcoholic solution, after having been left standing for some time, deposited a red-coloured amorphous body, insoluble in water, only sparingly soluble in alcohol, ether, and benzol, but somewhat better soluble in light petroleum oil. [This is a very ill-defined expression for a solvent, since light petroleum oil, also known as ligroine, is certainly not always of the same composition, and may, therefore, in some instances, turn out not to act as a solvent.] The elementary analysis of the cyan-benzidine led to the formula $C_{11}H_{11}N_4$ — $C_{12}H_{12}N_4.2CN$.

Dimorphism of Tin.—C. Ramsberg.—The author refers, at great length, to some experiments made with tin by Dr. Fritzsche and other savants, and next states that he concludes, as to the dimorphism of tin, as a result of researches which prove that the sp. gr. of tin obtained by electrolysis, and also that of the metal after exposure to great cold, is far less (viz., from 7.143 to 7.195) than after the metal has been molten, when its specific gravity varies from 7.29 to 7.31. Its form (viz., crystalline) after fusion is, as far as can be ascertained, regular; but, at a very low temperature, this form is entirely modified, and belongs to the irregular system.

Naumann's Doctrine of the Caloric of Atoms, and on Horstmann's Criticism thereon.—E. Budde.

Bulletin de l'Académie Impériale des Sciences de St. Petersburg, Vol. xv. (Nos. 1 and 2), May and June, 1870.

These numbers contain the following original papers relating to chemistry and collateral sciences:—

Action of Light upon the Tissues of some Mono- and Di-Cotyledonous Plants.—A. Batalin.—This lengthy essay, illustrated by several woodcuts, contains an account of experiments made with the view to ascertain the effect of the action of direct and diffused sunlight on the development of the different parenchyma plants are histologically composed of.

Determination of the Weight of a Cubic Decimetre of Water at 4° C.—H. Wild.—This memoir contains the results of a series of experiments made with the view to ascertain what precision is attainable in practice as regards the determination of the absolute weight of the cubic decimetre of distilled water at 4°; this value the author finds to be within 1 milligram. The paper also contains some observations, deduced from the author's researches, in reference to the labours of the International Committee for Decimal Weights and Measures, and the making of standard types of the same.

Lignite Found near Sméla, District of Kijew, and the same Mineral occurring near Jelisawetgrad, District of Cherson (Russia).—G. von Helmersen.—A lengthy geological paper, chiefly of local interest only.

Complete Arrangement for Compensating for Temperature with the Weighing or Balance Barometer.—H. Wild.—Illustrated with diagrams.

New Researches concerning the Remains of Mammalia found in the Altaic Cavern, a Contribution to the Quaternary Fauna of the Russian Empire.—F. Brandt.

The Sponges of the White Sea and Arctic Ocean.—N. M. von Maclay.

Chondrodite Crystals from Finland.—N. von Kokscharow.

Crystals of Greenockite.—N. von Kokscharow.—Two crystallographical essays.

Deviation of Plumb-Line caused by the Attraction of the Caucasian Mountains.—J. Stebnitzki.

Bayrisches Industrie und Gewerbe Blatt, June, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Earthen- and Crockery-Ware which is Injurious to Health.—L. Buchner, E. Erlenmeyer, and C. Stüzel.—This lengthy paper is a report made by the authors to the Bavarian Minister of Commerce and Public Works, concerning the means by which, in the manufacture of earthen- and crockery-ware, the use of enamels containing lead as a flux may be either entirely avoided, or rendered innocuous, by the use of a very limited and small quantity of oxide of lead in combination with other substances, so as to prevent the glaze being acted upon by weak acids, such as, for instance, vinegar.

Occurrence, Preparation, and Technical Application of Glycerine.—C. Scheuer.—This very lengthy monograph contains all that is known relating to this subject, but does not mention any new researches made by the author, who has taken great care to produce an excellent and exhaustive compilation.

Black Dyeing of Horn without the Application of Boiling Heat.—C. Burnitz.—The objects made of horn, and ready for use, but not yet polished, are placed in a lye of caustic soda or potassa, and left therein until a portion of the surface has been dissolved, which may be readily detected by the somewhat fatty feeling the horn assumes when touched with the fingers. The objects are next washed in pure fresh water, and afterwards passed through Lucas's aniline black. After having been dried, the objects are washed, and, lastly, polished.

Washing and Exhaustion of Precipitates and other Substances.—Dr. Bolley.—The author applies, instead of hot and boiling liquids (water, alcohol, ether, benzol, sulphide of carbon, acetic acid),

the vapours of these fluids, in the following manner:—On the funnel containing the substance and filter to be washed or exhausted is placed another funnel of the same size (it is best that both funnels should have ground edges, but this is not indispensable, fixed by means of a sufficiently wide vulcanised india-rubber band. Through the neck of the upper funnel, steam, or the vapour of any of the above-named liquids, is made to pass, by connecting, with suitable tubing, the neck of the said funnel with a flask containing the fluid, which is kept boiling. The author states that, although steam, for instance, and the other vapours exert some pressure upon the filter, it rarely breaks; and his experience is, that, for washing precipitates (oxide of iron, for instance), hot steam works far more efficiently than hot water; while, for the purposes of exhausting substances, say, with alcohol, ether, &c., the vapours of these fluids act far more rapidly, effectively, and economically than the liquids at their boiling-point do by themselves.

Les Mondes, September 1, 1870.

Curious Facts relating to Holtz's Electrical Machine.—Dr. Morren.—The author, in a brief note addressed to the reverend editor of the above-mentioned periodical, states that he has obtained what he calls several electrograms (although not precisely specified, these appear to be a kind of photogram, but produced, not by the action of light, but by that of electricity). These electrograms exhibit—The manner electricity is distributed and seen on a positive, as well as negative point, also on a sphere of varying diameter; the electric movements which can exist in a hollow sphere electrified with positive and negative electricity; the manner electricity is distributed on different parts of the machine while in action, while giving off long, short, or middle-sized sparks, and also with or without condensers.

Iron and Hydrogen.—Dr. Klein.—The author, a pupil and collaborator of Professor Jacobi, of St. Petersburg, states, that the iron obtained by electrolysis is not, as has been often thought, the pure metal, but, on the contrary, a compound or mixture of iron and hydrogen, which, when heated to redness, gives off an enormous amount of that gas, and becomes, while greatly increasing in bulk, a silver-white, very soft, ductile, and malleable metal, which decomposes water readily below its boiling-point and oxidises most rapidly.

Curious Circuit of Lightning at Valenciennes.—Rev. F. Moigno.—At about 6 p.m. on the 27th of July last, lightning struck, and splintered to match-wood, the mast of a vessel lying in the canal; thence the lightning wended its way to an iron foundry, and, after traversing it for its full length, escaped along the iron stove-pipe placed in the office of the foundry; thence it proceeded up the steeple of St. Gery, entering there, through a broken glass-pane, the room inhabited by the tower watchman. In that room, it (the lightning) fell upon a galvanic battery, employed to convey, by means of electricity, the movements of the clockwork to the townhall clock, situated at several hundred metres' distance, causing such havoc and disturbance through the connecting wires that it was supposed the lightning had fallen on that building. Leaving the steeple of St. Gery, the lightning first fell on the house of an artist, and, after having broken some panes of glass therein, turned to the clock-tower of the college, melting, without any breakage, several panes of glass, and turning other panes of glass into a mass of curiously-coloured non-transparent substance; and, lastly, issuing again near the canal, slightly struck a soldier on duty there, and disappeared in the water. It is clear that, without special knowledge of the topography of the town above-named, it is not well possible to imagine this curious circuit, which, however, represents a broken line, having a basis of an arc of about 45°, and a total length of about 700 metres.

Polytechnisches Journal von Dingler, first number for August, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

The Electric Clock.—Dr. Arzberger.—With engravings.

Gold, Platinum, and Silver, as Applicable to the Ornamentation of Porcelain, Glass, and other Substances.—Dr. H. Schwarz.—This paper treats, at great length, on the commercial preparations of the metals alluded to, as manufactured for the purposes of being applied to china, porcelain, &c. The paper is too lengthy for any useful abstraction.

Observations on Dr. Bischof's Paper concerning the Fire-Resisting Properties of Clays.—Dr. Richters.

Action of Nitric Acid upon Toluoline.—M. Ballo.—This paper contains the results of some theoretical discussions elucidated by a lengthy series of formulae, with the view to prove that it may be possible to obtain, by the action of nitric acid upon toluoline, a nitro-kresol; but, practically, the author found that this was not attainable.

Testing Beer for the Presence of the Bitters of Quassia, Wormwood, and Marsh-Trefoil.—L. Enders.—The beer to be tested is first evaporated on a water-bath to the consistency of a syrup; to this is added strong alcohol, whereby the dextrose is precipitated; the liquid is filtered, and the filtrate again evaporated, to extract consistency. This extract is again dissolved in strong alcohol, and mixed with ether, for the purpose of removing glucose. The liquid having been filtered, the ether is evaporated, and the residue taken up with weaker alcohol and precipitated with acetate of lead. (a.) The precipitate containing the lupuline and hop-resin is filtered off, washed with water, and, after having been suspended in some distilled water, is decomposed by sulphuretted hydrogen. The sulphide of lead is collected on a filter and washed with alcohol; the joint liquids are again evaporated to dryness, and the residue treated with chloroform. Water

is added to this solution, and the chloroform is driven off by evaporation, whereby hop-resin is separated. The aqueous solution, from which the hop-resin has been separated by filtration, yields, on evaporation, in case it contains lupuline, as with genuine beer it ought, a bitter-tasting acid residue, soluble in alcohol, ether, and chloroform, the weak alcoholic solution of which is precipitable by acetate of lead, not so by tannin, and not yielding, with an ammoniacal silver solution, a metallic mirror. (b.) The liquor which ran off from the lead precipitate is first treated with sulphuretted hydrogen, to remove excess of lead; the liquid, having been filtered, is gently heated, to expel excess of sulphuretted hydrogen gas. There is next added to the liquid an aqueous solution of tannic acid; the ensuing precipitate will contain (if they were present) the three other above-named bitters. This precipitate is next while yet moist, mixed with carbonate of lead (white-lead, the original says), dried, exhausted with boiling alcohol, filtered, the filtrate evaporated to dryness, and the residue extracted with pure ether. (a.) The ethereal solution is evaporated to dryness. When the dry residue is mixed with concentrated sulphuric acid, it exhibits, on careful addition of water, a bluish violet colouration, yielding, when boiled with ammoniacal silver solution, a metallic mirror (absinthine). (β.) The substance which remains insoluble in ether, but is soluble in alcohol, and precipitable by tannin, but not by acetate of lead, is menyanthin (from *Menyanthes trifoliata*, marsh-trefoil), when it yields, on being warmed with ammoniacal silver solution, a metallic silver mirror; but, if this last reaction fails, quassine is present.

Annales de Chimie et de Physique, July, 1870.

This number contains the following original memoirs and papers:—

Expansion of Gases.—A. Cazin.—The continuation and concluding portion of this lengthy essay. This portion contains the following sections:—Description of a series of experiments; experiments with air; experiment with carbonic acid; observations on the expansion from 9 to 1 atmospheres; modifications of the apparatus, and description of the mode of experimenting; degree of correctness of the method; influence of the dimensions of the reservoirs; lowering of the temperature in the preceding experiments; experiments wherein p_1 varies and p_2 remains constant; conclusion.

Composition of Skin, the Modifications it Undergoes by Tanning, and the Fermentation of Tannin in Tan-Pits.—A. Muntz.—This paper is a somewhat enlarged reproduction of the author's memoir on this same subject, published in the *Comptes Rendus* of December 20th, 1869, and quoted in the *CHEMICAL NEWS*, vol. xx., p. 321.

Researches on the Glyceric Combinations.—L. Henry.—This paper treats more especially on glyceric trihydroxydine; and the author reviews the results of the labours of a great many scientific chemists on this substance, and finally concludes by stating that he has obtained a trihydroxydine, $C_3H_5Br_3$, a neutral liquid of an ethereal and not unpleasant odour; colourless; sp. gr. at 10°, 2.407; insoluble in water boiling at about 220°; and identical in properties with tribromide of allyl.

Study on the Molecular Action Founded on the Theory of Capillary Action.—C. A. Valson.—This very lengthy memoir is divided into the following chapters:—Introduction; on the curved lines known as "indicatrix lines"; method of experimenting; résumé of the experimental results; conclusions, and laws of modulus.

NOTES AND QUERIES.

Decomposition of Fulminate of Mercury.—Can any of your readers inform me of a safe process for the decomposition of fulminate of mercury? I wish to obtain the mercury in the metallic state.—C. H.

Assaying of Nickel.—Can any of your readers who are, or may have been, students at the School of Mines give me an outline of the assaying of nickel and cobalt ores, also arsenical ores, as practised at the said school?—A STUDENT IN METALLURGY.

Analysis of Old Yellow Metal.—(Reply to "Copper.")—We have referred to a number of works on chemistry, but do not find anywhere quoted what you desire. Unless the information occurs in the *Revue Maritime et Coloniale* or in the *Annales des Mines*, we believe your only chance of obtaining the analysis you wish for is to have them executed for you. The works referred to may be inspected at the Library of the Commissioners of Patents.

TO CORRESPONDENTS.

Guy's Hospital.—In our paragraph respecting the successor to Dr. Taylor, we should have stated that Dr. Debus and Dr. Stevenson are appointed joint Lecturers on Chemistry.

Exams.—There is no Examination. Fill up the certificate sent by post and forward it to the Secretary, Burlington House, Piccadilly, W.

B. K.—The *Revue des Cours Scientifiques de la France et de l'Etranger* is published at 17, Rue de l'Ecole de Médecine. Messrs. Bailière could probably get it for you.

B. W. Gibson.—Received.

Cook.—An advertisement would be the best way of acquiring the information.

Liverpool Royal Infirmary School of Medicine.—In our Students' Number, for J. C. Brown, B.Sc., read J. C. Brown, D.Sc.

TECHNICAL EDUCATION.

SCIENCE AND ART DEPARTMENT.

Royal College of Science for Ireland,
Stephen's Green, Dublin.

SESSION 1870-71.

This College supplies, as far as practicable, a complete Course of Instruction in Science applicable to the Industrial Arts, especially those which may be classed broadly under the heads of CHEMICAL MANUFACTURES, MINING, ENGINEERING, and AGRICULTURE.

A Diploma of Associate of the College is granted at the end of the Three Years' Course.

The Course of Instruction is recognised by the Secretary of State for India as Qualifying for Appointments in the Engineering Department.

There are Four Royal Scholarships, of the value of £50 each yearly, with Free Education, including Laboratory Instruction, tenable for two years; two become vacant each year. They are given to Students who have been a year in the College. There are also Nine Exhibitions attached to the College, of the yearly value of £50 each, with Free Education and Laboratory Instruction, tenable for three years; three become vacant each year. These are awarded at the Annual May Examinations of the Science and Art Department.

The Fees are £2 for each Course, or £10 for all the Courses of each year, with the exception of Laboratory, the Fee for which is £12 for the full course of Nine months, or £2 per month.

SUBJECTS OF INSTRUCTION.

Applied Mathematics, Mechanism and Machinery, Descriptive Geometry, Geometrical, Mechanical, and Engineering Drawing, Experimental Physics, Chemistry (Theoretical and Practical), Botany, Zoology, Geology and Palaeontology, Mining, Surveying, Agriculture.

The Laboratory is open for Instruction in Practical Chemistry, Metallurgy, and Assaying, from 10 to 4 o'clock every week day during the Session, except Saturdays and holidays.

The Session commences on Monday, October 3rd.

Programmes may be obtained on application to the Secretary, Royal College of Science, Stephen's Green, Dublin.

FREDERICK J. SIDNEY, LL.D., Secretary.

ANALYTICAL LABORATORY AND SCHOOL OF
TECHNICAL CHEMISTRY.

7, IRWELL CHAMBERS, OLDHALL STREET, LIVERPOOL.

Conducted by A. NORMAN TATE, Analytical and Consulting Chemist, and Chemical Engineer.

Established for Educational Purposes connected with Chemistry in its practical Applications to Manufactures, Commerce, &c.; for the performance of Analyses, Assays, and Chemical Investigations; and for affording information respecting the construction, &c., of Chemical Manufactures, and the conduct of Chemical Manufacturing Processes.

The Course of Instruction, in addition to the ordinary Chemical studies, comprises, as far as possible, all such other subjects as are necessary to give the scientific and practical information required in the Arrangement, Construction, and Management of Chemical Manufactories, and in the Application of Chemistry to Industrial Pursuits.

Students' Fees may be known on Application.

Plans, &c., for Chemical Apparatus and Manufactories are supplied, and the Erection of Plant and Buildings is superintended when required.

Lectures on Mineralogy applied to Geology and the Arts are given by Professor TENNANT, F.G.S., at King's College, London, on Wednesday and Friday Mornings, from 9 to 10 o'clock, and on Thursday Evenings from 8 to 9, from October 7th, to Christmas, to which the public are admitted on paying the College Fees, namely, Two Guineas to the Morning Course, and One Guinea to the Evening.

The Students are accompanied by the Professor to the Museum of Practical Geology, the British Museum, and other Public institutions, and also on excursions into the country.

Mr. TENNANT also gives private instruction in Mineralogy and Geology at his residence, 149, Strand, London, W.C.

Chloride of Calcium (Purified Muriate of Lime), total insoluble impurities under $\frac{1}{4}$ per cent.

CHLORIDE OF BARIUM (Muriate of Baryta), free from Iron and Lead, total impurities, water excepted, under $\frac{1}{4}$ per cent.

GASKELL, DEACON, & CO.,

ALKALI MANUFACTURERS, WIDNES, LANCSHIRE.

PRACTICAL CHEMISTRY.

Laboratory, 60, Gower Street, Bedford Square, W.C.

Mr. Henry Matthews, F.C.S., is prepared to give Instruction in all branches of PRACTICAL CHEMISTRY, particularly in its application to MEDICINE, AGRICULTURE, and COMMERCE.

The Laboratory is open daily, except Saturday, from ten to five o'clock; on Saturday, from ten till one o'clock.

Mr. Matthews is also prepared to undertake ANALYSES of every description.

For Particulars and Prospectuses, apply to Mr. Henry Matthews, the Laboratory, 60, Gower Street, Bedford Square, W.C.

North London School of Chemistry, Pharmacy, &c.—For Instruction in Practical Chemistry and Evening Classes for the Study of Chemistry, Botany, Materia Medica, &c. Conducted by Mr. J. C. BRAITHWAITE, for thirteen years Principal Instructor in the Laboratories of the Pharmaceutical Society of Great Britain, and Demonstrator of Practical Pharmacy, Pharmaceutical Latin, &c.

Mr. Braithwaite, having taken the premises adjoining his house, has been enabled nearly to double the size of his Laboratories, and, at the same time, procure a large piece of ground which he has had laid out as a Botanic garden. Every facility is, therefore, offered to Students desirous of acquiring a practical knowledge of this branch of their education.

The Session 1870-1871 will commence on the 3rd of October, when the Laboratories will be re-opened at 10 a.m. for Instruction in Practical Chemistry as applied to Pharmacy, Medicine, Analysis, &c. Pupils can enter at any period. Terms moderate.

THE CHEMICAL and TOXICOLOGICAL CLASS will meet as usual every Monday and Thursday evening, at 8 p.m., commencing October 3rd.

THE LATIN CLASS for the reading of Physicians' Prescriptions, Cæsar's Commentaries, &c., every Tuesday and Friday evening, at 8 p.m.

THE BOTANICAL and MATERIA MEDICA CLASS, every Wednesday and Saturday evening, at 8 p.m. The usual EXCURSIONS for the STUDY of PRACTICAL BOTANY will be continued every Saturday, until further notice, at 10 a.m.

Fee to either of the above Classes, Half-a-Guinea per Month. Pupils can enter at any period.

Gentlemen Privately Prepared for the Examinations of the Pharmaceutical Society, and the "Modified Examination for Assistants," &c.

All Fees must be paid in advance.

Letters of inquiry should be accompanied with a stamped envelope.

Mr. Braithwaite receives a few Pupils to Board in his house.

Address—54, KENTISH TOWN ROAD, N.W.

AMSTERDAM EXHIBITION, 1869.

The GRAND DIPLOMA of HONOUR, being the First Prize, and SUPERIOR to the Gold Medal.

Liebig Company's Extract of Meat.—Paris EXHIBITION, 1867, TWO GOLD MEDALS; HAVRE EXHIBITION, 1868, THE GOLD MEDAL.—Only sort warranted perfect and genuine by BARON LIEBIG, the Inventor. "A success and a boon."—Medical Press and Circular. One pint of delicious beef-tea for 2d., which costs 1s. if made fresh from meat. Cheapest and finest-flavoured "stock" for soups, &c.

CAUTION.—Require BARON LIEBIG's signature upon every jar. Sold by all Italian Warehousemen, Grocers, Chemists, and Ships' Store Dealers; all Wholesale Houses; and of LIEBIG'S EXTRACT OF MEAT COMPANY (LIMITED), 43, Mark Lane, E.C.

NOTICE.—Various chemical analyses have been published purporting to show a fraction more of moisture to exist in the Company's Extract than in some imitation sorts. It is extremely easy to evaporate the water almost to any extent, but it is quite as certain that the fine meaty flavour which distinguishes the Company's Extract from all others would be destroyed if the concentration of the Extract were carried beyond a certain degree. Beef-tea made from Liebig Company's Extract with boiling-hot water will be found to be greatly superior in flavour, strength, and clearness, to any other sort. This explains the universal preference it obtains in the market.

This Extract is supplied to the British, French, Prussian, Russian, and other Governments.

Challenge to the World.—The Bristol Daily Times and Mirror, August 5th, has the following:—MESSRS. J. C. SWAN and Co., of 16, Queen's Square, in this city, have invented a pocket microscope, which is a marvel in all that such an instrument should be. It has great power, remarkable definition, and does not require focussing. The cheapness of the article will make it exceedingly popular when its merits are more widely known. It is called the "Bristol Microscope," and is a great credit to the inventor, as much for its extreme simplicity as its power. The Western Daily Press says: "The Bristol Microscope has a magnifying power of 200 times, &c., &c." The Western Daily Telegraph says: "The Bristol Microscope is the most compact and useful scientific instrument we have ever seen; it possesses extraordinary power, and is very easily managed, &c." The price of the Bristol Microscope is only 2s., or free by post, with printed directions, for 28 stamps.—Address, J. C. SWAN and Co., Opticians, 16, Queen Square, Bristol.

THE CHEMICAL NEWS.

VOL. XXII. No. 566.

ON A NEW METHOD OF OBTAINING CHLORINE.*

By HENRY DEACON, J.P.

It is well known that when a mixture of hydrochloric acid gas and oxygen is sufficiently heated, portions of the hydrogen and oxygen combine and some chlorine is liberated, and the proportion of chlorine can be increased by passing the hot gases over hot porous substances. The quantity of chlorine, however, at the best is inconsiderable.

The method now under consideration induces these reactions at much lower temperatures, and so actively that the whole of the hydrochloric acid gas can be decomposed and its chlorine liberated, or pure nitrogen can be obtained from atmospheric air by combining all its oxygen with the hydrogen of hydrochloric acid.

It consists in the employment of some substance over which the hot mixed gases are passed, the substance remaining unchanged, yet influencing the changes in the gases.

Copper salts possess this power in a very marked degree, and of them sulphate of copper is so convenient that I have generally employed it. But all the compounds of copper hitherto tried have proved to be equally active; many, of course, become changed by oxidation, or are converted into chloride, the change is generally slow, whilst the activity is continuous.

Sulphate of copper, however, comes out of this experiment unchanged. All the corresponding compounds of lead, except one, are also active, but require a higher temperature. The exception is the sulphate of lead, which thus contrasts singularly with the corresponding copper compound. All the manganese compounds at still higher temperatures are also active, but it is doubtful if with manganese the reaction is ever complete. At the high temperature requisite with manganese it seems probable that chlorine itself reacts on the water produced to re-form hydrochloric acid and oxygen.

A large number of experiments have proved that all that is necessary is to dip pieces of common red brick into a saturated solution of sulphate of copper and dry them. With these charged pieces tubes are filled, and the heated gases (hydrochloric acid gas and oxygen) are passed through the tubes.

The temperature at which the reaction is most active is about 700–750° F., but it is operative as low as about 400° F. If the temperature be raised to about 800° F., chloride of copper begins to volatilise. That is to say that, although no chloride of copper be originally employed, it is, under the circumstances, always formed and volatilised when the temperature reaches about 800° F.

The exact temperature is defined with some considerable reservation, as the difficulties of observation are very great. It is, however, believed to be correct within moderate limits, and, as might, perhaps, have been expected, the reaction depends quite as much, and with some probability more, upon the temperature of the mixed gases than upon the temperature of the influencing agent. In this way an indefinitely small particle of sulphate of copper, remaining itself at the end of the process unchanged and unremoved, can effect the liberation of the whole of the chlorine from an indefinitely large mass of hydrochloric acid gas.

In the first long-continued experiment one equivalent of copper gave upwards of 300 equivalents of chlorine, and was as active at the end as at the commencement.

* Read before the British Association, Liverpool Meeting, Section B.

It has been found that increasing the loading of sulphate of copper above a certain point on the pieces of brick does not increase their efficiency. To prove this, pieces of brick were carefully sorted as to size and used alone, and the minute amount of chlorine evolved from a heated mixture of the gases was noted.

Pieces of the same size were then boiled down with a given volume of a solution of sulphate of copper, dried and used in the same apparatus, under the same conditions, and the result noted. They were then charged with a second additional quantity of sulphate of copper, and the experiment repeated, and finally crystals of sulphate of copper itself, of the same size as the pieces of brick, were dried and used, and the result in grains of chlorine in the same time was the same in each of the experiments with copper.

In the experiments with the brick only, the quantity obtainable in the laboratory has not exceeded three per cent, whilst with copper, as before described, the whole of the chlorine has been set free. Further experiments have also shown that, at the same temperature, the same surface of copper compounds (and it is believed all other compounds follow the rule) gives the same quantity of chlorine in the same time, provided, of course, that sufficient heated oxygen and hydrochloric acid gas are presented to it. The truth of this law with copper compounds has been proved within very wide limits. The speed of the current of gases and the composition of the mixture of gases have been widely varied. The speed can be reduced until the chlorine evolved is the whole the hydrochloric acid gas contains, or increased till the chlorine evolved forms but a small percentage of the mass passing, yet the total weight of chlorine evolved from the same apparatus at the same temperature in the same time is constant. Of course if the gases were mixed with others exerting a chemical influence, the results would be varied, but with such gases as vapour of water, nitrogen, carbonic acid, and sulphuric acid gases, there is no change in the law. In point of fact, the atmosphere has been the source of oxygen almost always employed, therefore nitrogen has been constantly present, and vapour of water is one of the substances formed by the reaction, and must, therefore, always be present. Whilst the weight of chlorine remains constant, the percentage of work done will necessarily vary with the quantity of hydrochloric acid gas passed. If the current be so slow that the reaction is complete, then 100 per cent hydrochloric acid gas will be decomposed; but if double the quantity of acid gas be passed in the same time, only one-half of it will be decomposed, or only 50 per cent of its chlorine will be liberated, and similarly for other quantities.

For laboratory experiments we have used an ordinary glass combustion-tube. A little trough is made out of sheet-iron, a few iron borings are sprinkled at the bottom and the tube laid in them; heat is applied to the trough by a row of Bunsen's burners. The metal of the trough and the borings spreads the heat and secures a tolerably uniform temperature. The little pieces of brick employed with the tube are about the size of small peppercorns or large mustard seeds. A constant current of hydrochloric acid gas is obtained by using a lump of sal-ammoniac and strong vitriol in a bell hydrogen apparatus; the pressure of the gas evolved displaces the acid used, and prevents waste of material, and delivers the gas under pressure. The current of air has been obtained from the action of the Sprengel water-pump that does our laboratory filtering.

For ordinary experiments, the mixture of the gases can be regulated by dipping the two gas-delivery tubes into aqueous hydrochloric acid, and by counting the bubbles of gas from each tube. If the tubes are of equal diameter, and the same configuration, and immersed the same depth, a sufficiently accurate estimate can be formed of the proportions of the mixture. With a combustion-tube, not quite 2 feet long and about $\frac{1}{4}$ -inch bore, the reaction will be so complete, that the resulting gases, collected in a

2-ounce flask of white glass, exhibit very strongly the characteristic colour of chlorine. Of course the chlorine can be detected and estimated by the ordinary chemical reagents, when it is in far too small quantities to give an apparent colour in so small a mass. With due care, this experiment can be continued until the chlorine obtained is many hundred times equivalent to the copper employed; not a trace of copper will be volatilised, and, when the patience is exhausted or examination is desired, the sulphate of copper will be found intact and free from chloride of copper, fit, apparently, to continue active for an indefinitely long time. If, however, the experiment be watched through the tube from the commencement, and a piece of iodised starched paper be used to detect the first passage of chlorine in the washed gases, a change of colour will be detected in the heated sulphate of copper, simultaneously with the detection of the first chlorine. This tinge resembles the colour of heated chloride of copper, and remains constant during the experiment, but disappears as the tube cools. The known property of heated sulphate of copper to absorb hydrochloric acid gas appears, therefore, to be closely connected with this phenomenon. For more accurate experiments glass gasometers, containing the mixed gases in known proportions, and working with vitriol saturated with hydrochloric acid gas, were employed, and the current and time were, by these means, carefully regulated. The temperature, in the small scale, was ascertained, within certain limits, by the melting of enclosed morsels of metals and alloys of known composition.

I trust now to be excused for giving the reasons which led me to anticipate this reaction; for it is not a so-called accidental discovery, but, as regards chloride of copper and chloride of manganese, it was deduced from what I think a logical argument on known facts. I hope, also, to be excused in saying that, in making and applying this deduction, I was not aware that the idea of a general law of chemical action, under which this reaction appears to fall, had been originated by Mercer in 1842, before the meeting of the British Association in Manchester, and further elaborated by Playfair, in a paper read before the Chemical Society, and published in their *Transactions*, vol. iii. (1847); and, so far as I know, the subject, as regards a general law of action, still remains much as Playfair left it.

It is scarcely necessary to say the effect of any general law would be to remove a variety of chemical actions from the indefinite limbo of "contact action" or "catalysis."

Before going further, I will use Playfair's words to describe his own views and those of Berzelius, Liebig, and Mercer.

As typical of the class of reactions, Mercer's experiment may be taken. On dissolving 1 oz. of oxalic acid in $\frac{1}{4}$ a pint of water, at 180° F., and adding to this 1 oz. of colourless nitric acid of 1.30 sp. gr., no action ensues, but immediately commences on the addition of a proto-salt of manganese, as, for example, its oxalate or nitrate. These proto-salts of manganese influence a reaction, and are themselves unacted upon. Berzelius regarded this kind of power to be "a distinct electro-chemical agency different from other recognised powers," and he named it the "catalytic force."

Liebig viewed it as a dynamical action on the atoms of a complex molecule, conceiving that the activity of the atoms of a body in a state of motion may be communicated to those of another body in a state of rest.

Mercer's view was that catalytic bodies act by exerting a feeble chemical affinity on one of the constituents of the body decomposed.

Playfair says the catalytic body is, therefore, a substance which acts by adding its own affinity to that of another body, or by exerting an attraction sufficient to effect decomposition under certain circumstances, without being powerful enough to overcome new conditions, such as elasticity and cohesion, which occasionally intervene and alter the expected result.

Playfair's paper abounds with experimental illustrations, and is most suggestive.

The idea of the law which had occurred to me proves to be an extension of the much earlier idea of Playfair's.

With your permission I will explain it from my point of view, although, after the authorities quoted, I do so with much reserve.

It appears to me that the force we call chemical action is usually dealt with as if its operations were restricted to obtaining results strictly lying within the lines of direction of the forces applied. To illustrate this mechanically, a body may be supposed to be moved from a point in the north-east to another point in the south-west. Chemically, this would be said to be accomplished either by a force acting in that direction, or first by one force, which acted from east to west, carrying the body to the west, where, subsequently upon its arrival, it was acted upon by another force from north to south, carrying it to the same point to which it would have arrived had it moved from north-east to south-west direct. And where more forces than one are concerned in the movement of the body, the forces are supposed to unite in the same direction or line, by simple addition. In mechanics, the path of motion would be held to be the resultant either of two or more forces acting in the direction of motion, or of two or more forces acting in different directions, the difference of direction being no obstacle to the effect produced as the resultant.

My idea is that concurrent chemical forces unite, and are resolved into other equivalent forces, similarly with mechanical forces. A chemical result, therefore, may either be the resultant of direct forces, or the resultant of many indirect forces acting in many directions; and, also, the resultant of indirect forces may bring about a chemical result, which lies outside the path or direction of many, and, in some cases, perhaps, outside the path of all, the forces engaged. That is to say, we may deal with the composition and decomposition of concurrent chemical forces much in the same way that we deal with these problems in mechanics.

Two familiar chemical operations formed with me the basis of this idea, namely, the manufacture of sulphuric ether by the continuous process, and the manufacture of sulphuric acid. In the first of the two, a mass of vitriol is heated, and on it is poured a small stream of alcohol, or vapour of alcohol is passed over hot vitriol. The result is the decomposition of the alcohol into ether and water, the vitriol remaining unchanged. The ordinary explanation (I believe Liebig's) is, that this depends on the union of the acid and alcohol as sulphovinic acid, and the subsequent decomposition of this acid by heat into ether and water. But, at the temperature employed, sulphovinic acid cannot exist; how then can it be formed? Again, as to sulphuric acid making. The crystalline compounds formed by the union of some of the gases, and the chamber sickness, as it is called, are almost too familiar to dwell upon. Suffice it to say that, by a series of successive reactions, which, probably, most of us have seen beautifully illustrated on the lecture-table, it is said that sulphuric acid is formed. But, in the manufacture itself, what becomes of these compounds?

They are no sooner perceived, in however minute degree, than the manufacturer of either ether or of sulphuric acid hastens to destroy them, and if any of them ever are detected in practice the process is known to be out of order.

Sulphovinic acid is a reality—these chamber compounds are realities, but they are never seen in the successful process of manufacture. Although these compounds are unseen, the forces which would form them are there. Those forces are active too, for combination is the result of action, as motion is the result of force. A moving body and a chemical combination may each be sources of force, but there is a necessary distinction to be regarded between the exertion of force and the results which ensue when that force has been exerted. I have said these compounds

are unseen, and this word should be understood in its widest sense. No contrivance can detect their presence. What more is needed to prove their absence? The conclusion I draw is, they are not there, but the forces which would make them are there, and it is to the union or composition of those concurrent forces that the reaction is due as a direct result. That is to say, using my first mechanical illustration, the path followed by the bodies operated upon, is not that from east to west, which would first make these compounds, and then by the path from north to south in order to decompose them, and so yield at the south-west the product of materials which started from the north-east, but the path followed is direct from north-west to south-east. It is the direct and not indirect resultant of the concurrent forces engaged. Engaged, but not satisfied, for the same vitriol would react on indefinitely large masses of alcohol, and the same nitrous acid would cause the formation of indefinitely large quantities of vitriol.

Having conceived this idea of the action of chemical forces, I wished to prove it. But it seems to admit of only one form of positive proof, namely, that of time. I will continue the use of the illustration already adopted, viz., two forces acting in the same plane at right angles to each other, one north to south, the other east to west, and the object starting from the north-east and delivered in the south-west. If the path of the object as governed by the forces be first from east to west and then north to south, the time occupied in the entire journey will be the times of the two separate journeys added together. But, if it passes from the conjoint influence of the two forces diagonally, and direct from north-east to south-west, the time occupied will only be the time it would occupy to perform one of the journeys. So far I have been quite unable to adopt this proof. The first conditions are wanting. It cannot, I think, yet be said in what directions the forces lie. They may also be of different kinds, attractive and dispersive. The lines of force, although brought together by some medium, may, so to say, lay in different planes, and some may oppose and some assist. There is a further difficulty when bodies are considered to be in motion under the influence of forces of constantly varying intensity. The forces of attraction and repulsion vary probably in proportion to the square of the distances, and chemical force may follow the same law. The actual path of a body amidst a number of centres of force must, therefore, be curved, for with every change of position the relative intensity of the forces acting upon it must vary. This kind of proof seems, therefore, to be at present unattainable.

The next kind of proof—that of accounting for all known phenomena of the kind called catalytic—presupposes a knowledge of all the forces engaged in each reaction, and this knowledge I certainly do not possess. The remaining available proof was to apply the theory to known cases to foretell a hitherto unknown result.

This opportunity occurred when considering a proposition to obtain chlorine from chloride of copper by first heating it, whereby half its chlorine is set free, then oxidising it in a moist atmosphere, adding hydrochloric acid to it, and again heating it, when chlorine is again evolved, and the copper compound is left for another oxidation; and thus by constantly repeated, but distinct and consecutive, operations, the same mass of copper could be used for the production of large quantities of chlorine. The same principal material, chloride of copper, was also proposed as a source of oxygen. After it has lost half its chlorine and is oxidised, as just described, it yields oxygen on heating. Here, then, was the opportunity: hydrochloric acid and oxygen are each separately attracted and held at the same temperature, by the same body; and yet if both are previously united with the body, they are let go, but are divided into chlorine and water.

I argued that the forces concerned were acting, so to say, in the same plane; they were concurrent, and should therefore unite, and the resultant should be a direct and not

an indirect reaction; the wind and the current should carry the ship diagonally but directly, not first blow her across the stream, and then afterwards float her down it to her port. This was put to the test at my request and instigation by Dr. F. Hurter, the able head of our laboratory. The first experiment that was made in a hasty extemporised way yielded to equivalents of chlorine from one of copper employed. For convenience, I had suggested the use of oxide of copper, not chloride, and it was mixed with peroxide of manganese, partly to prevent fusion of the chloride of copper which we expected would form, and partly because I felt persuaded that chloride of manganese would react in the same way. This expectation was also subsequently proved to be correct, but it occurs, as was anticipated, at a much higher temperature. The conversion of these oxides into chlorides was so slow that at first we thought they were unchanged. The manganese was first acted upon and then the copper, but the oxidation of the hydrogen of the hydrochloric acid was the same first and last. A regular series of experiments were then decided upon, and all were performed by Dr. Hurter in our laboratory, and to this gentleman belongs much of the credit of the success attending the experiments hitherto made. I claim the discovery and the reasoning that led up to it, as before explained, but all subsequent progress has been the result of constant conference between Dr. Hurter, Mr. Eustace Carey, the manager of the works, and myself, and I am glad to have this opportunity of acknowledging the value of their assistance.

Although the discovery was made about three years ago, it has not yet been applied successfully as a commercial undertaking to the manufacture of bleaching-powder. The delay has arisen in great part from a long and serious illness which befell me, and partly from having previously engaged to put into operation at our works another and a very successful process, Mr. Weldon's, which was at first much nearer the bird in the hand than my own.

We are now vigorously working upon the subject on the large scale, and are more and more impressed with the value of the discovery, and believe the end of our difficulties is near at hand.

One of our first difficulties was to measure the speeds of the gases. Mr. A. E. Fletcher has shown how this can be done with the use of an anemometer of his contrivance, but we found many difficulties in its use in a rough way. His table of speeds for pressure, and other information of that kind, have, however, proved invaluable. Mainly by Dr. Hurter's assistance, a different form of anemometer was devised. An example lies on the table. It was described a few months ago before the Philosophical Society of Manchester by another gentleman as his original idea. We have no reason to doubt that the same idea has occurred to others as well as ourselves; we believe, however, our instruments were in use at a much earlier date. We can speak in high terms of its value; and perhaps some members may be glad to learn of Holtzapffel's paper scales, each ruled separately by a dividing engine. Any arbitrary division can be had, so that very good verniers and scales for home-made instruments of many kinds may be obtained at small cost.

The next obstacle was a serious one, and has only been recently overcome: it was the difficulty of measuring the temperature of the gases; it being important to know it accurately and quickly, within small limits, and the range being too high for mercury. The quenching in water of masses of copper heated in the furnace, and measuring the heat gained by the water, as proposed by Siemens, is accurate, but too tedious to be of use as a constant watchman. All the ordinary pyrometers, consisting of a tube of brass outside an iron tube or rod, with some mechanical indicator of the difference of expansion between the two metals, were proved to be defective at temperatures above 500° F. The brass tube elongates both permanently and irregularly. Being deceptive, they were worse than useless.

We have recently employed rods of brass and iron instead of tubes, making the iron carry the brass, instead of, as usual, the reverse, and, up to temperatures not over 1000° F., with complete success; a very important difficulty is therefore removed by simple means. It is not easy to say why the apparently trifling change is so effective. We think the errors in ordinary pyrometers of this class arise, in part, from a permanent change in the diameter of the brass tube, which takes place with every material change of temperature, and partly from a stretching of the tube when it is softened by heat. The rod, being solid, is more uniformly heated through its diameter, and is better able to resist change of dimension in the direction of the diameter, so does not alter by mere heating and cooling. It is relieved from strain, and therefore does not stretch; and two similar-sized rods being compared together, the errors tend to correct each other.

An apprehended difficulty proved to be groundless. Nitrogen is, of course, largely mixed with the chlorine, and, it was supposed, in making bleaching-powder, might prevent the saturation of the lime with chlorine. But good bleaching-powder is easily made, even with very moderate decomposition, and consequent large dilution of chlorine, simply by employing large surfaces of lime in series, the strong gases passing over the nearly saturated lime, and the spent gases over fresh lime.

The undecomposed hydrochloric acid is removed by water, and this aqueous acid dissolves mere traces of chlorine, so that all the chlorine produced is available for operating with.

The reaction itself is a source of heat—4 volumes of hydrochloric acid and 1 volume of oxygen yielding 2 volumes of water and 2 of chlorine; that is, 5 volumes are reduced to 4 volumes. With the atmosphere as the source of oxygen, the nitrogen brings up the volumes to about 9 volumes reduced to 8. 10,679 units of heat are given out, using Favre and Silbermann's figures of 34,462 units, resulting from the union of oxygen and hydrogen, less 23,783 units required as the combining heat of hydrogen and chlorine. The water and nitrogen present absorb this heat and reduce the apparent temperature; but this evolution of heat is a material assistance in making up for the loss of heat in the decomposing apparatus from radiation.

Taking the hydrochloric acid gas as it is evolved by the ordinary salt-cake apparatus, it is found that air is normally present in sufficient quantities to liberate all the chlorine; and, as there is a wide margin for dilution in either direction, without any material evil, another anticipated difficulty disappears.

There is no occasion to be constantly watching the mixture of gases.

It has been found that iron resists, very completely, the action of the chlorine in the decomposing apparatus. A common iron gas tube is produced which has been exposed to the heated chlorine for about a fortnight, and others have been so exposed for months without any appreciable wear; iron, therefore, is freely employed, and possesses many evident advantages.

The heat of the gas requires to be carefully regulated; with too much heat, chloride of copper is sublimed; if the heat be too low, the reaction decreases, and at length stops. We use a regulator consisting of brickwork, carefully enveloped, to prevent radiation. It acts as a reservoir to absorb and yield surplus heat; and we can easily maintain a current of gases for twenty-four hours within a variation of 25° F., and without skilled attendance.

The real difficulties, as far as we know, are three. First, the large bulk of gases; these need a large apparatus. A manufacturer making 40 tons daily of sulphate of soda would have to deal with about 1,100,000 cubic feet of these gases daily; he already deals with that bulk. It is not proposed to increase the quantity evolved in the process; the difference will be in the way of treating it. In preparing the vitriol for the manufacture of his 40 tons

of sulphate of soda, he has dealt with at least 3,400,000 cubic feet of gases in vitriol chambers.

Chemical manufacturers are therefore trained to deal with gases in magnitude, and we apprehend little difficulty on this account.

Secondly, there is the preliminary heating of the gases, and this is a question mainly of durability of apparatus; it is the only part in which at present there is much wear and tear. Brick- or tile-flues, heated exteriorly, are objectionable because of the numerous joints and leakage. It is proposed to adopt Cowper's method of heating hot-blast for iron furnaces—viz., to heat a mass of brickwork, then cut off the fire to heat another mass, and pass the gases through the heated mass; by the time that it is cooled, the second mass will be heated, when the current of gas will be reversed, and so on.

We think well of this plan, but are at present trying cast-iron pipes, and, with large surfaces, moderately heated, have every prospect of success.

The last difficulty known to us arises from the volatilisation of some iron with the hydrochloric acid, and we have not yet thoroughly examined these substances. Of course they are assumed to be, and probably are, chlorides of iron, but there are peculiarities about their appearance needing investigation. The peculiarity is mainly this: they are not deposited until they reach the copper-salts.

Until very recently, we thought it was merely a condensation in a cooler part of the apparatus; but this is not the case. The difficulty itself is, that the passages become gradually filled up, and the first part of the apparatus has to be cleaned out. We find, when the copper-salts are warm enough, the sublimate we take to be chloride of iron disappears, and is replaced by sesquioxide of iron, an obturant equally objectionable. We think it is now proved that this deposition, in the first instance, is a formation depending upon the presence of chlorine; it occurs only where free chlorine is present, and is soon deposited. The sesquioxide of iron no doubt results from the decomposition of this substance in the presence of oxygen, chlorine, and moisture, at a higher temperature. The remedy we have adopted, and are now engaged in proving, is, to have the reactive filling arranged with vertical openings over an empty space (we use agricultural drain-pipes one on another). The deposit is always pulverulent, and does not interfere with the reaction of the copper-salts. These vertical channels allow the heavy dust to descend into the space below, whence it can be withdrawn, and also afford easy access for clearing from the top.

The employment of leaden, instead of iron pans, for the decomposition of the salt, and the adoption of Cowper's plan of heating the gases, would prevent the introduction of iron to a very great extent. This combination forms part of our army of reserve, for use in case of need.

The gases are propelled by the aid of a chimney-draft, and we shall probably always prefer to draw, rather than to force them. The colour of the resulting gases gives a good indication of the success of the decomposition; and the proportion of hydrochloric acid in the air is easily ascertained, when desired, by a finger-pump, drawing known quantities at each stroke through a normal alkaline solution coloured with litmus. The greater number of strokes required before the blue colour is changed to red, the more air and less acid gas is present, and *vice versa*.

In conclusion, I would give expression to some of the concurrent forces resulting in the reading of this paper.

First, we believe this process will soon materially affect the commercial industry of chlorine, and we desire to direct the attention of our fellow manufacturers to it; and, lastly, believing this little-worked mine of composition and decomposition of chemical forces offers rich prizes to skilled investigators, I desire to revive its consideration. May it not be said the skilled chemist, like the skilled navigator, can so use the union of forces, that, by aid of the wind

itself, he sails nearly in the wind's eye? And, to carry the metaphor one stage further, may it not be hoped, perhaps anticipated, that, by the application of new combinations of forces, a chemical "steam power" will make future chemists masters at will over chemical winds and tides?

REPORT OF THE COMMITTEE ON THE CHEMICAL NATURE OF CAST-IRON.*

We regret to have to report that it has not been in our power, during the past year, to make any important progress in the investigation of the chemical nature of cast-iron, which was entrusted to us.

In the appendix to the report which we submitted last year, a process was described by which pure iron could be prepared in considerable quantities, and it was intended to apply this process at once to the preparation of the material necessary for our investigations. The apparatus and arrangements required for this purpose have, however, been unavoidably in a dismantled condition during the greater part of the year, in consequence of the reconstruction of the laboratories of St. Bartholomew's Hospital. They are now again in working order, and it is hoped that the experiments will be resumed without much further delay.

Numerous experiments have been made with a view to ascertain whether the pure iron sponge, prepared by the process above referred to, can be converted, by welding, into thoroughly solid masses, without detriment to the purity of the metal. Hitherto, the results obtained, though instructive in connection with the physical properties of the pure metal, have not been of promising nature in the particular direction desired. It is contemplated, however, to continue these experiments, with the aid of facilities which, we believe, will be available for this purpose, at the Royal Arsenal, Woolwich.

For the foregoing reasons, we beg leave to suggest that the re-appointment of this committee be recommended, but we do not consider it necessary to apply for a grant of money on this occasion.

F. A. ABEL, DAVID FORBES, A. MATTHIESSEN.

September 1st, 1870.

ON THE LANCASHIRE ALKALI TRADE.†

By W. GOSSAGE.

At the meeting of the British Association for the Advancement of Science, held in Manchester in September, 1861, I had the honour to read a paper, entitled "A History of the Soda Manufacture," before the Chemical Section of that body. I now propose to submit a brief supplement to that paper, in which I will notice the various improvements connected with the processes of manufacturing soda, as then existing, during the lapse of nine years since that period; also some details of the increase which has taken place in the extent of this important manufacture during that time.

As one of the most important facts connected with the soda manufacture, I must not omit to notice the passing of a legislative measure, entitled "The Alkali Act, 1863," rendering it imperative that all manufacturers decomposing common salt, for the production of sulphate of soda, should condense not less than 95 per cent of the hydrochloric acid gas evolved by such decomposition. In my former paper I described fully the means which I had devised and carried into successful operation in the year 1836 for effecting such condensation, and these means are now

adopted universally by the soda manufacturers, and so successfully that not only do they comply with the legislative requirements of condensing 95 per cent of the hydrochloric acid set free, but in many instances this condensation exceeds 99 per cent. It has been very fortunate for the manufacturers as well as for the public that Dr. R. Angus Smith was selected by the Government to undertake the duties of chief inspector under the Alkali Act of 1863. This gentleman, with his able staff of district inspectors, has assisted greatly in promoting the effective working of the system of condensation. The able reports submitted annually to the two houses of Parliament by Dr. Smith contain the fullest details of the working of this legislative enactment, and it may be fairly expected that when the same amount of care and attention has been applied to subduing the bad effects resulting from other noxious vapours, chemical manufactories will be relieved from the charge of occasioning injury to their vicinities.

The most important use for hydrochloric acid obtained by such condensation is the manufacture of hypochlorite of lime, or bleaching-powder, the demand for which has taken an extraordinary development since the introduction of straw, esparto grass, and some other substances than rags for the manufacture of paper.

At the date of my last paper, the chlorine required for the manufacture of bleaching-powder was obtained by the action of hydrochloric acid on native peroxide of manganese. Recently Mr. Walter Weldon, of London, after long-continued devotion of time, labour, and money, has succeeded in perfecting a process by which peroxide of manganese is obtained from the chloride of manganese, produced by the action of hydrochloric acid on peroxide of manganese. Mr. Weldon effects this object by causing the chloride of manganese to be decomposed by hydrate of lime, thus producing hydrated protoxide of manganese, which he converts into peroxide of manganese, by causing streams of atmospheric air to be forced through the fluid mixture of protoxide and water. When in this state of minute division the protoxide of manganese absorbs oxygen from the atmospheric air and becomes converted into peroxide. Mr. Weldon has found it essential for successful working, that not only a sufficient proportion of lime be used to precipitate the oxide of manganese, but that such an excess be employed as will be sufficient to form a chemical compound with the peroxide of manganese as thus is produced, which compound Mr. Weldon designates as manganite of calcium. This process has been successfully carried into practice in this district, also in that of Newcastle, and it has already been adopted by some of the largest manufacturers of bleaching-powder in both these localities.

It is well known that to obtain one equivalent of chlorine by the reaction of hydrochloric acid on peroxide of manganese, it is essential that two equivalents of hydrochloric acid should be employed, one of these yielding chlorine, the other chloride of manganese.

We have had the advantage of hearing from Mr. Deacon a full explanation of his very scientific process for the manufacture of chlorine without the use of manganese, by which process the whole of the hydrochloric acid is decomposed into chlorine. By this process each equivalent of hydrochloric acid yields an equivalent of chlorine.

Mr. James Hargreaves, of Widnes, has also devised means for producing chlorine without the use of oxide of manganese. He has a process for the separation of phosphorus from the iron slag produced in the puddling operation of the iron manufacture. In carrying out this process the iron slag is treated with hydrochloric acid, and thereby protochloride of iron in solution is obtained as a bye-product, which is evaporated to dryness, producing dry protochloride, and this, by slow application of heat with access of atmospheric air, becomes perchloride, which undergoes decomposition, yielding chlorine and peroxide of iron. This process also yields an equivalent of chlorine for each equivalent of hydrochloric acid employed.

In my former paper on the soda manufacture, I took

* Presented to the Secretary of Section B., British Association, Liverpool.

† Read before the British Association, Liverpool Meeting, Section B.

occasion to remark that nearly all the sulphur used in this manufacture (the cost of which is about equal to two-fifths of the total cost of materials required) was re-obtained in combination with calcium, forming what is expressively designated as "alkali waste."

I noticed, also, that this presented a problem worthy the attention of my juniors for its solution. Dr. Ludwig Mond, a German chemist, has made the nearest approximation to the solution of this problem with which I am at present acquainted. Mr. Mond's process consists, in the first instance, in causing atmospheric air to be brought into intimate contact with the alkali waste, as this is left in the lixiviating vats after treatment with water. This is effected by the use of a ventilating fan, which forces air into the lower part of the vat, under a false bottom. The air percolates the mass of waste, and a portion of its oxygen becomes absorbed by the sulphide of calcium yielding soluble hyposulphite of calcium, and at the same time a portion of the sulphide of calcium becomes converted into soluble polysulphide of calcium. The oxidation is so regulated, as regards its extent, that the resulting solution, when this is obtained and treated with hydrochloric acid, should yield sulphide of hydrogen and sulphurous acid in such proportions as to mutually decompose each other, yielding free sulphur at the same time that the second equivalent of sulphur contained in the hyposulphurous acid of the hyposulphite of lime is set free. A very pure sulphur, almost absolutely free from arsenic, is obtained by this mode of working.

This process has been carried out successfully by various manufacturers, but, unfortunately, the quantity of sulphur obtained is far short of that contained in the waste, and I consider the problem I have mentioned still remains as an exercise for ingenuity and perseverance.

In my former paper on the soda manufacture, I gave some particulars of the means I had adopted for obtaining copper and silver from the burned residua of copper pyrites which had been used for yielding sulphur to manufacture sulphuric acid. This mode of working has been superseded by a process devised and carried out by Mr. Henderson. This process consists in mixing a small proportion of salt with burned pyrites, previously ground to a fine powder, and exposing this mixture to a low red heat, either in open reverberatory or closed furnaces, through which a current of atmospheric air is allowed to pass. By these means the small portion of sulphur which has escaped being consumed in the burned pyrites becomes oxidised, producing sulphate of iron, which decomposes common salt, yielding chloride of copper and sulphate of soda, which are obtained in solution on lixiviating the product with water. The copper is then precipitated from the solution by means of iron, and is obtained in the metallic state. A large quantity of oxide of iron is obtained as a residuum from the lixiviation. This is sold to the iron smelters for the production of iron. These operations are carried out very extensively by the Tharsis Metal Company, at Glasgow, Newcastle, and Widnes. There are also several other establishments engaged in the same business in the neighbourhood of Widnes—amongst others that of the Widnes Metal Company, where Mr. J. A. Phillips has carried out successfully a process invented by Mr. Santler, of London, for extracting gold, silver, and lead from the burned residua of copper pyrites.

In the year 1861, during the negotiation of the French treaty of commerce, it was estimated that the total quantity of salt decomposed in Great Britain for the production of soda was 260,000 tons per annum. Of this quantity, 125,000 tons were decomposed in what is called the Newcastle district, and 135,000 tons in the Lancashire district. According to the returns of the Alkali Manufacturers' Association, for the year 1869, the total quantity of salt decomposed for the manufacture of soda was 326,000 tons, thus showing an increase of 66,000 tons, or 25 per cent on the total. Of this quantity, the decomposition in the Newcastle district, in 1869, was 142,000 tons, which, being compared with 125,000 tons in 1861, shows

an increase of 17,000 tons, or 13·6 per cent. The decomposition in the Lancashire district is returned as 184,000 tons in 1869, against 135,000 tons in 1861, showing an increase of 49,000 tons or 36 per cent. It would thus appear that the total quantity of salt decomposed for the manufacture of soda in the Lancashire district in 1869 exceeds by 30 per cent the total quantity decomposed in the Newcastle district during the same year.

One of the most important applications of soda to other manufactures is that of the production of soap, and it may be interesting to notice the increase in the production of this article, which is so essential to cleanliness, and, therefore, to civilisation. In the year 1852, when the excise duty on soap was finally abolished, the total production of soap in Great Britain was equal to 1600 tons per week, less than one-half of which was produced in the Lancashire district. From some inquiries which I have recently made I am satisfied that the present production of soap in the Lancashire district is fully equal to the total production in 1852. We may, therefore, infer that the production of this article has doubled during the past eighteen years.

I have shown from official documents that the production of soda in the Lancashire district exceeds by 30 per cent that of the Newcastle district, and when we remember the immense number of manufactories at work in Lancashire for the production of chemical substances to be used in bleaching, dyeing, calico printing, &c., we must adopt the conclusion that Lancashire is the largest seat of chemical manufactures in this country.

Dr. Roscoe said that, by way of supplementing Mr. Gossage's remarks, he might say that, in the ten years previous to 1861, the increase in the amount of salt decomposed was 300 per cent—that is to say, in the year 1852 there were 38,600 tons, while in 1861 the quantity was 135,000.

ON THE BEHAVIOUR OF CASTOR OIL WITH PETROLEUM AND PARAFFIN OILS.

By HARRY NAPIER DRAPER, F.C.S.

THE liquids used in these experiments were:—

Petroleum oil	0·810 sp. gr.
Paraffin oil	0·817 " "
Petroleum spirit	0·710 " "

Each of these dissolves, at 16° C. in all proportions, the following fatty bodies:—

Almond oil.	Theobroma oil.
Olive oil.	Palm oil.
Rape oil.	Cod-liver oil.
Linseed oil.	Lard oil.
Sesame oil.	Cocoa-nut oil.
Croton oil.	Ergot oil.

And as these taken collectively typify a very large series of fatty oils, it may reasonably be supposed that there are but few exceptions to the rule of solubility. Castor oil, however, forms a very remarkable one. This oil which is on the one hand, separated from all others by its complete solubility in alcohol of sp. gr. 0·829, is, on the other, so insoluble in the petroleum hydrocarbons, that the addition of even one-half per cent to either paraffin oil or refined petroleum at 16° C. causes turbidity. At 50° C. a large quantity is taken up, but separates immediately as the liquid cools.

But though castor oil is itself insoluble in the petroleum oils, it exercises itself a solvent action upon them, which is remarkable for being limited in a very unusual manner.

If castor oil be shaken with excess of petroleum spirit at 16° C. and allowed to rest, it will be found to form two layers, the upper of which consists of petroleum spirit alone, and the lower of a mixture of petroleum spirit and castor oil in equal volumes.

The results of several experiments have shown that—
100 vols. of petroleum spirit dissolve 100 vols. of castor oil.
100 " " oil " 67 " "
100 " paraffin oil " 67 " "

If the hydrocarbons be agitated with castor oil in any larger proportions than these, the excess separates, but the increase in volume of the castor oil is always the same, so that castor oil does not affect the separation of any particular hydrocarbon.

There is no difference in the behaviour of East-India and Italian castor oils.

This reaction cannot, unfortunately, be used as a test for the presence of castor oil in other oils, because the presence of other fatty bodies in any quantity renders castor oil soluble in the petroleum oils. It will, however, distinguish this series of hydrocarbons from benzol, in which castor oil is soluble in all proportions.

Dublin, August, 1870.

EXAMPLES FOR PRACTICE IN QUANTITATIVE CHEMICAL ANALYSIS.*

By FRANK H. STORER,
Professor in Massachusetts Institute of Technology.
(Continued from p. 109).

EXPERIMENT IV.—Estimation of Water and Magnesia in Epsom Salt.

To prepare a sample of crystallised salt proper for analysis, heat 40 or 50 grms. of commercial Epsom salt with as much boiling water as may be needed to dissolve it, filter the boiling liquid into an evaporating dish, and leave the latter at rest until its contents have become cold. A coating of crystals will then be found adhering to the bottom and sides of the dish. Pour off the liquor from above these crystals and fasten the dish in a vertical position, in such manner that most of the mother liquor may drain away and the crystals be left nearly dry. Press the moist crystals repeatedly between folds of thick filter paper until they become so dry that they no longer stick to the paper. Then weigh out about 4 grms. of the crystals for analysis.

To determine the water in the crystals proceed as in the analysis of gypsum (*Expt. II.*; CHEMICAL NEWS, vol. xxii., p. 99).

In our experiment 3.664 grms. of freshly crystallised Epsom salt lost 1.879 grms. of water on being heated. Or, in terms of per cent, 51.28. Theory requires 51.22 per cent.

To determine the magnesia, transfer the ignited salt from the crucible to a beaker of about 700 c.c. capacity, dissolve it in some 400 c.c. of cold water, stir into the solution 40 or 50 c.c. of a tolerably strong solution of chloride of ammonium together with enough ammonia water to make the liquid slightly alkaline. Finally, add a quantity of a solution of ordinary phosphate of soda, and stir the mixture thoroughly, taking care not to touch the sides of the beaker with the stirring rod. The precipitate of phosphate of magnesium and ammonium which falls is a crystalline substance liable to adhere firmly to any scratch, or even mark, which the stirring rod might leave upon the sides of the beaker in case it were allowed to rub against the glass. The liquid must not be heated at any time, lest the formation of the crystals be hindered.

As soon as it appears that a slight excess of the phosphate of sodium has been added, cover the beaker and leave it at rest for twelve hours or more, in order that the crystals of the double phosphate may all be deposited. Then pour the liquid and precipitate upon a six-inch filter, and wash the precipitate with a mixture of three parts water and one part strong ammonia water until a few drops of the filtrate show only a slight cloudiness on

being mixed with a drop of nitric acid and a drop of nitrate of silver. Dry the precipitate, ignite it intensely in a porcelain crucible, and weigh the pyrophosphate of magnesium which remains.

There was obtained 1.672 grms. of $2\text{MgO}, \text{P}_2\text{O}_5$ (= 0.6025 grms. MgO). This result indicates 16.44 per cent of magnesia in the Epsom salt. Theory requires 16.26 per cent.

The sulphuric acid could of course be determined by precipitating it with chloride of barium, as in *Expt. II.*, or it may be estimated by the difference, as was done in the present case. The complete analysis was as follows:—

	Found.	Theory.
MgO	16.44	16.26
SO_3 (by difference)	32.28	32.52
$7\text{H}_2\text{O}$	51.28	51.22
	100.00	100.00

(To be continued).

ON A STEAM FILTER PUMP.*

By Dr. J. WALZ.

THERE are many locations in which the Bunsen filter pump cannot be employed on account of a deficiency in the water supply. For such cases a plan has been devised by Dr. Walz of New York, editor of the *Manufacturers' Review and Industrial Record*, which is described in that journal, and has been proved in practice to be efficient.

The accompanying cut shows the outline section of the most important part of the apparatus. A is a tube supplied with steam from a flask or boiler; B is connected with the exhaust of the filter. By the action of the steam jet identical with that known as the "exhaust" in a locomotive, a vacuum is produced in

B, C, D. By sliding the tube, A, back and forward in the cork, B, an adjustment can be given to the outlet within D, so as to secure the best effect.

The conditions of best effect here are identical with those in the inner nozzle of the Giffard injector when it is starting its water supply from a lower level, and no doubt the proportions found most efficient in that instrument will prove also in this.

CHEMICAL TABLES ACCORDING TO THE THEORIES OF MODERN CHEMISTRY.†

By Professor ALBERT R. LEEDS.

(Continued from page 40.)

In the *Comptes Rendus*, vol. xx., p. 1047, will be found another series of careful and laborious determinations of certain atomic weights by Pérouze. Other valuable contributions to our knowledge in this direction will be found in the *Bibliothèque Univ. de Genève*, vol. xvi., by De Marignac, and by Erdmann and Marchand, in the *Zeitschrift für Prakt. Chem.*, vols. xviii., xxvi., xxxi., and xxxiii. A brief synopsis of the processes and results which are given in the above-cited memoirs, is appended to Miller's "Elements of Chemistry," Part II., p. 859. For special contributions to our knowledge of the atomic weights of antimony, cadmium, and lithium, consult *Chem. Centr.*, 1857, pp. 454 and 897; *Wien. Acad. Ber.*, vol. xxv., 118; *Zeitschrift*.

* Communicated by the Author. From the *Massachusetts Teacher*.

† Communicated by Professor Morton. From advance-sheets of the *Journal of the Franklin Institute*.

für Prakt. Chem., vol. lxxii., p. 338; *Ann. Chem. Phys.* [3], vol. li., p. 103; *Silliman's Am. J. Journ.* [2], vol. xxviii., p. 349; *Ann. Chem. Pharm.*, vol. cxxi., p. 93; *Comptes Rendus*, vol. liv., p. 366. Abstracts and references concerning the atomic weights of cesium, rubidium, and thallium will be found in the *Fahresber. der Chem.* In a recent number of the *Journ. für Prakt. Chem.*, 1869, Rammelsberg has re-calculated the atomic weights of tantalum and niobium (columbium) after the analyses of Rose and De Marignac. In the *Am. Journ. Sci.* [2], vol. xli., p. 53, Dr. Genth has published the re-determination of the atomic weight of cerium, by Dr. C. Wolf, and his results are here accepted as representing at present the closest approximation to the truth. For the atomic weights of erbium and yttrium, consult the memoir, by Bahr and Bunsen, in the *Ann. Chem. Pharm.*, vol. cxxvii., p. 1, and for terbium, that by Delafontaine, same journal, vol. cxxiv., p. 99. Two series of independent analyses are given by Winkler, in the *Journ. für Prakt. Chem.*, vol. cil., p. 273, the mean of which makes the atomic weight of indium 37.81. To vanadium, Roscoe assigns an atomic weight of 51.33 (*Phil. Mag.* [4], vol. xxxv., p. 307).

De Marignac assigns to didymium the atomic weight 47.92 (*Ann. Chem. Phys.* [3], vol. xxxviii., p. 148; to lanthanum the concordant results of Mosander, Holzmänn, and R. Hermann give 46.4 (*Journ. für Prakt. Chem.*, vol. lxxv., p. 321, and vol. lxxii., p. 385). Our information concerning ruthenium is almost entirely derived from the labours of Claus (*Ann. Pharm.*, vol. lvi., p. 257, vol. lix., p. 234, and vol. lxiii., p. 259, which makes its atomic weight 52.1. From a careful perusal of the chemical testimony adduced in the foregoing memoirs, as to the true atomic weights, Table III. of the atomic weights, according to ancient chemistry, has been derived. Where the chemical testimony appeared equally strong for different values of the atomic weight of any element, the law of specific heats and isomorphism have afforded help in the decision. It is not expected that others would be impressed in precisely the same way by a similar examination of these data. But it is hoped that the table here given will commend itself as an accurate and impartial summary of our present knowledge, and that it may be taken with safety and advantage as a groundwork for the tables which follow. Appended to the atomic weight of each element is the authority upon which it rests. In every case, the result of the analyses themselves is given, and not the atomic weight deduced from them in accordance with Prout's law, or any other theoretical consideration. Neither has the mean of the atomic weights obtained by several observers for any element been taken, because we do not thus necessarily arrive at a truer approximation.

Upon Table III., as a foundation, Table IV. has been built up, in agreement with the hypotheses of modern chemistry. To mention what these hypotheses are, and in what manner they have been applied to the atomic weights of each element, would be vastly beyond the reach of our present purpose. They involve the labours of Kolbe, Kekulé, Hofmann, Frankland, Williamson, and a host of others who have projected and established the new chemical system.

In some cases, the atomic weights which are given as those of Berzelius, in the Table, according to ancient chemistry, are half of what he himself adopted. In regard to the atomic weights, the opinions of Berzelius, in many instances, were juster than those of the chemists who followed him—they retrograded.

TABLE I.

Atomic Weights according to the Original Observers.

ELEMENT.	BERZELIUS.		OTHER OBSERVERS.	
	O = 100.	H = 1.	O = 100.	H = 1.

Zirconium	419.728	67.260	[419.728, when, as regarded by Berzelius, zirconia is Zr_2O_4 .] According to De Marignac and Dumas, Zirconia is ZrO . Then the atomic weight is 22.4.	

(To be continued).

NOTICES OF BOOKS.

Alkali Act, 1863: Sixth Annual Report, by the Inspector (Dr. R. Angus Smith, F.R.S.) of his Proceedings during the year 1869. Presented to both Houses of Parliament by command of Her Majesty. London: 1870.

THE work before us, in common parlance a *blue book*, will, we greatly fear, not receive that due appreciation of its merits which its highly valuable contents deserve. It is not merely an official report of duties often performed simply according to a well-established routine; on the contrary, we have to deal, in the first place, with a scientific monograph on the condition of the air in various places exposed to the influence of manufactures, and also on the condition of the air where manufactures do not exist. The eminent author has attempted to give, and we may even say, judging from the pages before us, well succeeded in giving, such an account of the state of the atmosphere of any given place, that it is possible to say, without difficulty, whether it may be considered as tainted by manufactures, or whether it has a large amount of organic matter in it. Moreover, an answer has, to some extent, been given to the question as to the condition of that matter, as it is of importance to distinguish it from that caused by manufacturing processes. The modes by which the air has been studied are—(1) By the usual examination for the gases, oxygen and nitrogen; (2) carbonic acid; (3) ammonia; (4) ammonia from albumenoid matters; (5) nitric acid; (6) rapidly oxidisable matters; (7) slowly oxidisable matters; (8) chlorides and sulphates; (9) acidity; (10) examination of the rain, including an estimation of all the substances mentioned as in the air, the gases excepted.

The author's work is so full of interesting matter, and the results are so condensed, that we regret to say that the ensuing *embarras de richesse* prevents us quoting here more than a mere drop, so to say, from an ocean of valuable and highly-interesting results. The average quantity of hydrochloric acid in rain, in parts per million, varies from 0.97 at Darmstadt, to 25.74 at Runcorn; while at London it is 1.25, and in Scotland (sea-coast and inland country places) 7.95. The distance from the sea mainly governs the amount of chlorine. Total acids of chlorine and sulphur, the relation to the average of that from Row, Dumbartonshire, being taken as unit (1) we find—England (inland places), 1.4; Scotland (sea-side and inland places), 2; Germany (some specimens), 3.4; London, 4.4; Liverpool, 9.4; Runcorn, 10; Newcastle-on-Tyne, 10.4; near an alkali works, 15.1. The acids here meant are

both the combined and the uncombined. *Air—Total Acid* (relation to Blackpool taken as 100).—London, 289; St. Helen's, 474; Manchester, 527; Underground Railway (Metropolitan), 1483. *Air—Hydrochloric Acid* (relation to Blackpool taken as 100).—Buxton, 247; London, 320; St. Helen's, 516; Underground Railway (Metropolitan), 974. *Air—Sulphuric Acid* (relation to Blackpool taken as 100).—Didsbury, 320; London, 361; Manchester, 549; Underground Railway (Metropolitan), 1554. *Air—Total Ammonia* (relation to Inellan taken as 100).—London, 117; a bedroom, 179; Glasgow, 202. These scanty instances, taken at random from the large number of tabulated results, may convey some, but, we are bound to say, a very imperfect, idea of the contents of the first and main portion of this valuable treatise. The second portion of this work is devoted to the subject of the condensation of hydrochloric acid at the alkali works.

Our readers will recollect that the Alkali Act of 1863 was made law with the view of enforcing a proper system of condensation of hydrochloric acid, and to prevent neglectful escape of gas. This end, we are glad to see, has been very well arrived at; and, as a proof of the genuine desire on the part also of the manufacturers, to attain a high efficiency of condensation, we are informed that, at two works in the Newcastle-on-Tyne district, permanent structures have been erected, at a cost of £10,000 for each alkali work. There are added to this valuable Report large lithographic plates representing the structures alluded to.

CORRESPONDENCE.

FILTRATION OF STRONG ACIDS.

To the Editor of the Chemical News.

SIR,—As some of your readers may, like myself, have found considerable difficulty in the filtration of the strong mineral acids, I take this opportunity of acquainting you with the mode by which I think this can best be accomplished.

Into the narrow part of an ordinary glass funnel, spun glass (such as is used in making tails for glass birds) is closely packed, and over this is sprinkled ground glass to the depth of a quarter of an inch, care being taken that both the funnel and glass are perfectly clean. About 4 ounces of boiling water are then allowed to pass through the filter, which is then allowed to dry, and, previous to being used, is moistened with a pure specimen of the acid to be filtered.

A filter so constructed is as efficient as any with which I am acquainted, is very durable and cheap, while, from the fact that these acids do not act on glass, freedom from contamination during the process is perfectly ensured.

I may mention that such filters, or the materials necessary for their preparation, may be obtained at Mr. Motherwell's, 73, Union Street, Glasgow.—I am, &c.,

JAMES ST. CLAIR GRAY, M.B., C.M.,

Assistant to the Professor of Forensic Medicine, Glasgow University.

MISCELLANEOUS.

Hydrated Chloride of Aluminium as an Antiseptic.—We learn that a strong solution of this substance is coming into use as an antiseptic. The advantages which it possesses are that it is non-poisonous and devoid of smell, being, at the same time, a powerful antiseptic. It is to be met with in commerce under the name of "choralum."

The Ladies' Medical College.—The seventh annual session of study will commence with an introductory

address by J. A. R. Newlands, Esq., F.C.S. The address will be given at St. George's Hall, at three o'clock on Monday, October 10th, and the chair will be taken by Dr. Ross. The general public are invited to be present. Intending students should apply to the Lady Secretary of the Female Medical Society, at the Offices, 164, Great Portland Street, W.

New Works on Chemistry, &c.—The following are amongst the new works Messrs. Churchill are preparing for publication:—"A Manual of Botany," by Robert Bentley, Professor of Botany, King's College, London, and to the Pharmaceutical Society (second edition). "A Laboratory Text-Book of Practical Chemistry, or Introduction to Qualitative Analysis;" a guide to the course of practical instruction given in the laboratories of the Royal College of Chemistry, by W. G. Valentin, F.C.S. "Handbook of Volumetric Analysis, or the Quantitative Estimation of Chemical Substances by Measure," by Francis Sutton, F.C.S., Norwich (second edition, much enlarged). "The Year-Book of Pharmacy," containing the proceedings at the yearly meeting of the British Pharmaceutical Conference, and a Report on the Progress of Pharmacy, which will include notices of all Pharmaceutical papers, new processes, preparations, and formulae published throughout the world.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

[In consequence of the war on the Continent, several of the foreign journals have failed to reach us; we shall, however, give abstracts of them as soon as they are received.]

Comptes Rendus des Séances de l'Académie des Sciences, September 12, 1870.

This number contains the following original papers and memoirs relating to physico-chemical and allied sciences:—

What are the True Chemical Agents to be Used as Antiseptics? M. Faye.—This paper contains a lengthy review on the mode of action of several substances used as disinfectants and antiseptics, and especially as regards the action of phenol (carbolic acid); but the author himself states that he did not think he could say anything new. A discussion arose on this subject, the speakers being MM. Dumas and Chevreul. The former *savant*, in the first place, observed that the author had forgotten that carbolic acid was used largely, and that its application was compulsory in some instances, as well as the use of bleaching-powder. Phenolic acids, said the eminent speaker, in a double way—viz., by arresting the decomposition of albuminous and other organic compounds, in a manner somewhat analogous to tannin; and, secondly, by killing organic, as well as organised, germs and spores of all sorts—and thus acts as antiseptic. The speaker advocates the simultaneous application of chlorine (fumigations) and of carbolic acid. M. Chevreul spoke at length on the difference of mode of action of various antiseptics and disinfectants, calling, first, attention to the fact that sulphurous acid and sulphuretted hydrogen, when mixed together and decomposing each other, are mutually disinfectants; that hydrochloric acid and ammonia are in a somewhat similar relation to each other; that charcoal acts as antiseptic in a different manner—viz., by its capillary action; while the action of carbolic acid is chiefly confined to the material source of bad smell, but not to the bad smell actually itself. The venerable speaker next entered into a series of details of researches made by him as far back as the year 1809, on the action of tannin and tanning materials, and on the peculiar action exerted upon animal matters even by such substances as chloride of iridium, bichloride of mercury, chlorine-water, salts of alumina, glucina, and others, all of which possess, in a greater or less degree, astringent taste, and a peculiar property of combining with animal matters and, as consequence thereof, acting as antiseptics and antimasatics.

Observatory at Montsouris.—H. Sainte-Claire Deville.—This *savant* communicates, with great regret, that, in consequence of the operations for the defence of Paris, this establishment has been dismounted, the instruments, books, and records having been placed in

safety, by order of Admiral Méquet, who is the commanding officer of that portion of the fortifications wherein this observatory (partly a wooden building) is situated.

Proper Means of Counteracting the Effects of Insufficient Food.—M. Rabuteau.—This paper, although strictly belonging to physiology, contains some very valuable matter on the beneficial action of coffee and cocoa. The author records a series of experiments and facts taken from actual daily experience; and he suggests that man may live for several months, and keep active, strong, and healthy, by consuming daily 150 grms. of a mixture (dry) of—Powdered cocoa, 1000 grms.; infusion of coffee, 500; infusion of tea, 200; sugar, 500 grms. The two infusions, as strong as can be made, to be evaporated to dryness previous to being mixed with the rest of the substances; so that the whole weight of this 2200 grms. would be only about 1600 grms., and would be sufficient food for ten days, to be taken mixed with some boiling-water. The author states that it is highly agreeable, he having purposely experimented with this mixture upon himself while abstaining from other food.

Journal für Praktische Chemie, No. 13, 1870.

This number contains the following original memoirs and papers:—

Simple Method of Separating the Acids of Niobium and Ilmenium from each other.—R. Hermann.—The author describes, at length, a process of separation of the bodies alluded to, which is based upon the more difficult solubility of the double fluoride of potassium and ilmenium, as compared with the solubility of the double salt of potassium and niobium, the former requiring 20 parts of water at 10° for solution, while the latter is completely dissolved by 15 parts of that fluid at the same temperature. The author also describes a great many of the soda-salts of both acids.

Composition of the Columbite from Bodenmais (Bavaria).—R. Hermann.—This paper contains the lengthy description of the method of analysis employed for determining the constituents of a mineral which, in 100 parts, contains—Stannic acid, 0.36; tantalous acid (tantalic *sicure*), 24.23; niobic acid, 36.93; ilmenic acid, 18.84; protoxide of iron, 14.11; magnesia, 1.27; oxide of copper, 0.13.

Composition of Ferro-Ilmenite from Haddam, Connecticut, U.S.—R. Hermann.—The mineral alluded to is a tough, compact substance, without any appearance of crystallisation; black-coloured; non-transparent; sp. gr. 6.28; and containing, in 100 parts—Stannic acid, 0.50; tantalic acid, 40.95; hypo-niobic acid, 16.23; hypo-ilmenic acid, 23.74; protoxide of iron, 14.30; protoxide of manganese, 4.28; and very small quantities of tungstic and titanac acids.

Composition of Samarskite.—R. Hermann.—This mineral, also belonging to the same series as those above alluded to, was found to contain, in 100 parts—Stannic acid, 0.35; titanic acid, 7.39; tantalic acid, 7.19; hypo-ilmenic acid, 19.84; hypo-niobic acid, 25.10; thorina, 4.47; yttria, 14.0; protoxide of uranium, 10.58; protoxide of iron, 10.70; magnesia, 0.34.

The above-quoted papers are valuable on account of the exhaustive description which is given of the methods of analysis of these very complex native compounds.

On Isoclase and Kollophane, two New Phosphates.—F. Sandberger.—The author begins by stating that, for more than eighty years there has been, in the mineralogical collection at Würzburg (Bavaria), a specimen kept labelled as "white arsenic," from Joachimsthal; it occurred to him that this might be an error, especially as the mineral did not exhibit quite the characteristics of white arsenic. After referring, at length, to purely mineralogico-crystallographical particulars, the following analysis is quoted of this mineral, the sp. gr. of which is 2.92—Water expelled at 100°, 2.06; water lost at red heat, 18.53; lime, 49.51; phosphoric acid, 29.90; formula, $4\text{CaO} \cdot \text{PO}_4 + 5\text{H}_2\text{O}$. The author states that he does not doubt that this mineral has really been found at Joachimsthal, in Bohemia, and desires that the attention of the Austrian mineralogists should be directed to that locality, where, perhaps a larger quantity of this mineral may occur. Kollophane is a peculiar mineral occurring at Sombrero (an island belonging to the United States), and consisting, in 100 parts, of—Water expelled at 100°, 3.36; water expelled at red heat, 1.66; lime, 50.70; magnesia, 0.80; phosphoric acid, 39.70; carbonic acid, 3.96.

The following subjects are all communicated by Dr. Böttger:—

Anthracen Orange.—While experimenting on the preparation of alizarine from anthracen, the author found a new compound, the constitution of which he has not yet fully ascertained; but the new body contains nitrogen, and is obtained by first preparing a nitro-compound of anthrachinon by treating that substance, in pure state, with a mixture of equal parts of very concentrated nitric and sulphuric acids, and submitting it to a temperature of 40°. The anthrachinon dissolves; and, as soon as dissolved, the liquid is poured into a large quantity of water, by which operation the pure nitro-compound is precipitated as a bulky, yellow-coloured, flocculent body. This, having been collected on a filter, and washed, is next placed in a porcelain basin, and there is poured over it a solution of protoxide of tin in caustic potassa or soda. This solution first causes the appearance of an emerald-green coloured fluid, which, on continued boiling, deposits the beautiful cinnabar-red coloured substance. This, after having been collected on a filter, and well washed and dried, fuses at about 225°, and sublimes as a beautifully red-coloured crystalline matter, soluble in acetic ether, acetone, chloroform, aldehyde, ordinary ether, alcohol, and wood spirit. This pigment is also soluble, without decomposition, in strong sulphuric acid, as well as in nitric acid (sp. gr. 1.2).

Behaviour of Anthrachinon to Nascent Hydrogen.—When anthrachinon is treated with pulverised metallic zinc and a boiling

solution of caustic potassa or soda, it is reduced to anthracen, with the exhibition of a very brilliant red colouration, which only subsists as long as it is in contact with zinc.

Simple Method for Purifying Metallic Arsenic.—In order to restore to this metal its bright aspect, and also for the removal of any slight coat of suboxide which may adhere to it, the author advises that the metallic arsenic should be boiled for a few minutes in a moderately strong solution of bichromate of potassa, slightly acidified with sulphuric acid. The metal is next first washed with water, and then with alcohol or ether, and lastly placed in a small tube closed at one end, and sealed immediately after the arsenic has been put into it. Phosphorus, which has been kept a long time under water, and has become thereby coated with a whitish yellow crust, may be treated in the same way, when it becomes quite colourless again. The phosphorus should be, of course, carefully treated, so as to prevent its ignition; and, after having been well washed with cold water, should be preserved in water freed from air by having been previously boiled for a long time and cooled in a well-closed vessel.

Behaviour of Protochloride of Copper when Electrolytically Decomposed.—When protochloride of copper is placed in weak hydrochloric acid, and submitted to electrolysis, the electrodes being made of copper, the anode becomes covered with snow-white crystals of chloride of copper, while there is deposited on the cathode a thick layer of very loosely-adhering spongy metallic copper. When the latter is well washed, and next placed in a small flask along with a filtered solution of bleaching powder (hypochlorite of lime), that salt is partly decomposed, yielding, at first, very pure oxygen gas, but afterwards a gas (not specified) which extinguishes the light of a burning taper.

Very Sensitive Test for Hyposulphites.—Dissolve 1 decigram. of very pure permanganate of potassa, and 1 grm. of perfectly pure soda (prepared from sodium) in $\frac{1}{2}$ litre of distilled water; there is thus obtained a perfectly red-coloured liquid, which, upon the addition even of a very minute trace of any hyposulphite, becomes, at once, green. This test, the author states, is so delicate, that traces of a hyposulphite present in neutral sulphites may thus be detected.

Employment of Pulverised Magnesium as a Powerful Reducing Agent.—The chlorides of many metals are, when brought into contact with pulverised magnesium, readily reduced to the metallic state. Not only does this apply to the chlorides of gold and platinum, but even to that of zinc.

Preparation of Coloured Cements which Harden Rapidly.—The author takes a solution of silicate of soda (sp. gr. 1.298), and adds to it, whilst stirring, first pulverised and previously washed, lixiviated chalk, so as to form a thick mass, like butter, to which are added, for colouring purposes, the following substances:—Finely-pulverised sulphuret of antimony for black, iron filings for grey, zinc dust for whitish grey, carbonate of copper for bright green, oxide of chromium for deep green, cobalt blue for blue, red-lead for orange, vermilion for bright red, and carmine for a violet hue. This cement hardens within from six to eight hours, and may afterwards be polished, becoming like marble.

On Diastatic Ferments.—V. Wittich.

Bulletin de l'Académie Royale des Sciences, des Lettres et des Beaux Arts de Belgique, Nos. 6 and 7, 1870.

These numbers contain the following papers relating to physico-chemical and allied sciences:—

Reports on the Researches of MM. Cornet and Briart on the Millstone-Grit of Bracquesies (Hainaut, Belgium).—MM. d'Omalius, De Koninck, Dewalque, Horion, and Gosselet.—These papers are only of local geological interest.

Elastic Force of Liquefiable Gases.—M. Melsens.—This paper contains the results of a few researches made by the author while experimenting with condensed liquefied gases at higher temperatures, and employing, for the estimation of the pressure, metallic manometers. 1 liquid carbonic acid exerts, at 100°, a pressure equal to 228 and 86-100ths atmospheres (each atmosphere equal to 15 lbs. pressure per square inch). The author observes that, unless the space above the liquid gas be sufficient for the proper expansion of its vapour, the pressure, even at from 40° to 45° (equal to from 91 to 100 atmospheres), may rise to 300 atmospheres, and, consequently, become highly dangerous as regards the chance of explosions.

Existence of Natural Pits in Senonian Chalk Formation of Brabant.—F. van Horen.—This paper, illustrated by lithographed plates, treats on a subject before alluded to by us while quoting a former number of this periodical (see CHEMICAL NEWS, vol. xxii., p. 117).

Vitality of Beer Yeast, and on the Vitality of the Jennerian Vaccine Lymph.—M. Melsens.—As regards the beer yeast, the author states that his former experiments are fully confirmed (these experiments were made in 1866 and 1868). Jennerian vaccine lymph, exposed for an hour to artificially-obtained cold of -80°, was found to have preserved its vitality.

Geological Description of the Empire of Morocco.—M. Mourlon.—A lengthy essay, from which we learn that, among other industrially-valuable minerals, Morocco contains large deposits of rock-salt.

Annalen der Chemie und Pharmacie, July, 1870.

This number contains the following original papers and essays:—

Researches on Isomerism in the Benzol Series.—F. Beilstein and A. Kuhlberg.—Eleventh paper on this subject, divided into the

following sections:—Para-nitrotoluel, $C_6H_4(NO_2)CH_3$; meta-nitrotoluel, $C_6H_3(NO_2)CH_3$; dinitrotoluel-sulpho acid, $C_7H_3(NO_2)_2SO_3H$; ortho-nitrotoluel, $C_6H_4(NO_2)OCH_3$.

Action of Bromine upon Dichlorhydrine.—L. Carius.—After referring, at some length, to his former researches on this subject, the author describes two bodies, which result from the action of bromine upon dichlorhydrine. One of these substances is brom-dichlorhydrine, which it is difficult to obtain in pure state. The other body is dichlor-dibrom-acetone, $C_2H_2Br_2Cl_2O$; in hydrated state, it contains $(OH)_2$ in addition; it is a very hygroscopic body, which crystallises in large crystals soluble in alcohol and ether, but difficultly so in water and benzol. The paper contains an exhaustive account of the reactions and products of decomposition and derivatives of this body.

On Toluylen-Oxide, or Desoxybenzoine, $C_{10}H_{10}O$.—H. Limpriht and H. Schwanert.—This essay is divided into the following sections:—Toluylen-hydrate, $C_{11}H_{12}O$; toluylen, $C_{11}H_{10}$; acetyl-toluylen-hydrate, $C_{11}H_{12}(C_2H_3O)_2$; bromated toluylen-oxide, $C_{11}H_{11}BrO$; bibromated toluylen-oxide, $C_{11}H_{10}Br_2O$.

Benzilic Acid, or Diphenyl-Glycolic Acid.—Dr. A. Jena.—This paper contains the detailed description of benzilic acid, $C_{14}H_{10}O_4$, a solid, crystalline body, fusing at 150°, readily soluble in alcohol, ether, and boiling water, but difficultly in cold water. The author also gives an exhaustive account of a series of the salts of this acid, and treats, at length, on diphenyl marsh gas (*stumpfgas*), $C_{11}H_{14}$.

On Benzoine.—A. Jena and H. Limpriht.—This memoir is divided into the following sections:—Acetyl-benzoine; toluylen-alcohol; ethyl-benzoine; ethyl-benzilic acid, $C_{11}H_{11}(C_2H_3O)_2$.

On Dibenzoyl.—Dr. A. Jena.—This paper contains the critical review of the labours of various experimenters on this body, which, according to the author, is by no means easily prepared; and its existence seems, judging from the results of his labours, somewhat doubtful.

Homologues of Naphthalene.—R. Fittig and J. Remsen.—This lengthy treatise contains the following chapters:—Methyl-naphthalene, $C_{11}H_{10}=C_{10}H_7CH_3$; methyl-naphthalene-sulpho acid—

behaviour of methyl-naphthalene with oxidising agents; ethyl-naphthalene, $C_{12}H_{12}=C_{10}H_7C_2H_5$; ethyl-naphthalene-sulpho acid—

Contribution to Our Knowledge of some kinds of Sugar.—H. Hlasiwetz and J. Habermann.—This memoir, too lengthy, like most of the preceding, for any useful abstraction, treats on—Glucose; formation of gluconic acid, $C_6H_{12}O_7$; various salts of gluconic acid; sorbine; levulose; glycérine; phloroglucine.

Bibliothèque Universelle et Revue Suisse.—Archives des Sciences Physiques et Naturelles (No. 152), August 15, 1870.

This number contains the following original papers and memoirs relating to physico-chemical and collateral sciences:—

Notice on the Levelling and Survey executed with very great Precision in Switzerland.—MM. Hirsch and Plantamour.—This paper contains an interesting account of the labours of a committee of scientific men and engineers, who, acting upon the suggestion made at an international meeting held at Berlin, in 1864, under the presidency of General Baeyer, set to work to execute, in the Helvetian Republic, a complete and very accurate taking of levels and measuring of altitudes above sea level, and other geodesical labours. The observatory at Berne is situated at 572.14 metres above sea level; the cathedral of Fribourg at 588.66 metres; the town-hall at Chaux-de-Fonds at 989.35 metres.

Glaciar Strife observed on the Fontainebleau Sandstone, near Paris.—E. Collomb.—A geological essay.

Bulletin Mensuel de la Société Chimique de Paris, August, 1870.

From the *procès verbaux* of the meetings of this Society published in this number, we learn that M. Cornu exhibited an instrument constructed with the view to measure the rotatory power of various substances. In this instrument, the plane of polarisation is not determined by the extinction of an image, but by the equality of the tint of two adjacent images. M. Riban states that he has worked with this instrument, and determined, by its aid, the rotatory power of different samples of amylac alcohol and derivatives thereof. The amylac alcohol obtained from rice exhibited, at 22°, a rotatory power equal to -1° 18'; -1° 19'; -1° 20'; and, after having been heated to 240° for forty hours consecutively, the rotatory power of this alcohol was yet equal to -1° 18'; and, even when the alcohol was heated to 300° for 27 hours, its rotatory power was not perceptibly decreased. The valerianic aldehyde obtained from the levogyric alcohol was dextrogyric, exhibiting a rotatory power equal to +2° 31' (the sp. gr. of the liquid, at 22°, being 0.799, and its boiling-point 93°). The valerianic acid derived from this aldehyde has a rotatory power of +1° 53' (the sp. gr. of the acid, at 22°, is 0.13). Amylen exhibits no rotatory power at all.

This number contains the following original papers and memoirs:—

Researches on the Ethers of the Arsenic Acids.—J. M. Crafts.—This paper is identical with that already quoted (see CHEMICAL NEWS, vol. xxii., p. 96).

Thermal Researches on Sulphur.—M. Berthelot.—The contents of this paper have already been referred to by us from the *Comptes Rendus* (see *CHEMICAL NEWS*, vol. xxi., p. 214).

New Method for the Synthesis of Organic Acids.—M. Berthelot.—The direct action of the oxidant of the ethylene and acetylenic carbides of hydrogen has the effect of first forming aldehydes and acetones. Any ulterior action produces monobasic acids, while the free hydrocarbons produce, under the influence of an alkaline permanganate, bitartric acids.

Meta-Naphthalene.—M. Berthelot, MM. Pelletier and Walter gave, some years ago, this name to a substance obtained from the tar from a resin gaswork. The author got, from M. Duclaux, a sample of this substance, preserved in the Museum of the Sorbonne, and found, on testing its properties, that those agreed with the description thereof published by the first-named gentleman (see *Ann. de Chim. et de Phys.*, 2nd series, vol. lxxii., p. 208, 1858). The author found, on further investigation, that this meta-naphthalene is a mixture of various carbides, none of which are identical either with phenyl or any of the well-known carbides which are obtained from coal tar. The substance in question, though beautifully crystalline, is an ill-defined mixture of a variety of bodies, the identification of which yet occupies the author.

An Aromatic Glycol.—E. Grimaux.—This lengthy paper is divided into the following sections:—Chloride of tolylen—

bromide of tolylen, $C_6H_4Br_2$; iodide of tolylen, $C_6H_4I_2$; diacetate of tolylen—

mono benzoate of tolylen—

tollylenic glycol—

Full Description of an Apparatus for Measuring Rotatory Power.—A. Cornu.

Decomposition of Oxalic Acid.—M. P. Carles.—This paper is mainly the same as the author's memoir published in the *Comptes Rendus*, and quoted in *CHEMICAL NEWS*, vol. xxi., p. 38.

Reply to the Critical Review of M. Reindel's Paper "On Ferrocyanides."—G. Wyruboff.

Some of the Properties of Albumen of Eggs.—A. Petit.—After referring to researches on this same subject published some years ago, the author treats on the action of acids and alkalis on albumen, stating that these reagents, while combining with albumen, produce its de-hydration, thus effecting a molecular rather than real chemical change. Animal charcoal (this is incidentally observed) has the property of absorbing albumen either from neutral, acid, or alkaline solutions; and this property, the author states, may be rendered available in analysis of vegetable and other substances.

Les Mondes, September 8, 1870.

General Extension of the Dry Season of 1870.—M. du Peyrat.—In a letter to M. Marié-Davy, the author states that he travelled from the island of Rouillon to Aden, thence through the Red Sea and the Suez Canal and the Mediterranean, and that during this twenty-six days' journey he has not felt a drop of rain. The ordinary rainy season at Rouillon has been absent this year altogether, no rain having fallen for eleven months consecutively. At Aden, no rain had fallen for eighteen months; and the large rain-water cisterns which are kept for the purpose of water supply there were quite empty, and all vegetation had disappeared. The same was seen at Suez, and along the canal, except in the valley of the Nile.

Health of Baron von Liebig.—We are happy to learn that the health of this eminent *savant* is so far restored that, although very weak, he is able to take some exercise, and intends to go shortly to Engadine, Switzerland, to stay there and enjoy the fresh country air.

Peat and Peat Bogs.—M. Diesbach. The author describes, at great length, a machine contrived to render the utilisation of peat as fuel a more readily manageable and, at the same time, economical business. He met present very successfully engaged in working the peat bogs of Cabonaye-Echaillon, Canton du Val de Suisse, Switzerland, producing a fuel which bears as much as absolutely dry wood. The author's machinery may be, perhaps, a boon to Ireland and other countries where peat bogs abound. From the statements made in this paper, there is no reason to doubt the efficacy, as well as the suitability of the process. Switzerland, moreover, is a country where fuel is scarce and cheapness a foremost requisite.

Constant Galvanic Element with One Liquid.—M. Delaurier.—This lengthy memoir illustrates with woodcuts, contains the description of a series of experiments made with this galvanic element. The author employs—Chromate of soda, 5 parts; water, 40; and sulphuric acid, 14 parts.

Journal für Gasbeleuchtung, July, 1870.

This number contains the following original papers and memoirs relating to chemico-physical and collateral sciences:—

Quantity of Water Yielded by Artesian Wells.—A. Thiem.—This paper is a lengthy essay reviewing the various algebraical formulae relating to hydrostatics and hydrodynamics.

Construction of Gas Meters according to the Metrical System; and on the Conversion of Gas Meters made upon the English and Rhénish Cubic Foot System into Metres according to the Metrical System.—T. Spilshagen.

Tin-Lined Lead Tubing.—Dr. Schilling.

NOTES AND QUERIES.

Soap Making.—I am a "soft soap" maker, and am anxious to have a book or treatise on the subject, or on soap-making generally and oils and fatty matters; can you direct me to the best? Also, particularly, the experiments of Mr. Clift (referred to in *CHEMICAL NEWS*, vol. x, p. 55) for the "sweetening of fish oils."—J. Y.

Artificial Alizarine.—I should feel favoured if any correspondent would kindly answer the following:—In the year 1861, provisional protection was obtained for the manufacture of artificial alizarine by Mr. T. J. Roussin. His process was by acting on what he called binitronaphthalene (obtained by causing naphthalene to react upon a mixture of azotic and sulphuric acids) with concentrated sulphuric acid and a metal. I should like to know if there was any foundation for this specification; if so, the nature of the colouring matter produced (specification, May 17th, 1861; No. 1266). These attempts are interesting now that the manufacture of alizarine has become an accomplished fact.—R. G. BENNETT.

Decomposition of Fulminate of Mercury.—(Reply to "C. H.")—This compound, which consists of 86 per cent of suboxide of mercury, and 14 per cent of fulminic acid, can be readily decomposed, so as to prevent any danger of explosion, by treating it, for instance, with hot nitric acid, whereby carbonic and acetic acids are formed and nitrate of mercury; or, by applying hydrochloric acid, whereby mercuric chloride and mercurous oxalate are formed. Moderately dilute sulphuric acid also decomposes it without detonation, but with rise of temperature and evolution of gas. The ensuing mercuric compounds can be readily converted into metallic mercury, by boiling with water in a clean iron vessel containing iron nails.

Hard and Soft Water.—Two or three weeks ago, a communication appeared in one of the leading journals, recommending the use of soft water in drinking and cooking purposes. Whatever value such an opinion may possess in a scientific point of view, there is reason to fear that, practically, it is not without danger to the public health. There is an idea, very prevalent amongst the non-informed portion of the public, that "soft water" means rain-water, which generally washes the blacks and other impurities from the tops of houses before it is drawn for use, and is certainly not the purest channel for conveying drinking-water into our houses. As the paragraph referred to was circulated freely at the time of its appearance, a few words of caution from you, Sir, may put people on their guard.—SANITAS.

Decomposition of Nitrate of Ammonia.—Would you inform me, through your answers to Correspondents, what the products or educts of the distillation of nitrate of ammonia are, besides N_2O ? Is it possible to get N_2O (nitric anhydride) and N_2O_4 (nitric oxide). A friend makes the N_2O for anaesthetic purposes, and employs three Wolff's jars; the first, nearest the retort, he has KHO or $NaHO$ in, to take up nitric acid or anhydride, which he says is formed (would not N_2O absorb it?); the other has a solution of SO_2FeO to purify the N_2O from N_2O_4 . Is he correct? From what I have read in Dr. Frankland and Townend, under the article N_2O , the equation is thus:— $NO_2(N^VH^V) = 2OH_2 + ON_3$ (Frankland's). Would you (if this equation is incorrect) give me a proper equation, and oblige.—A YOUNG STUDENT.

TO CORRESPONDENTS.

T. H. Page. The work is not published yet; it is a general work on Dyeing, &c.

Subscriber.—It is considered successful.

J. Steiner.—The allowance will be made.

W. Armit.—Received.

J. Edwards.—The notice appears in this week's number.

Water-glass, or Soluble Silicates of Soda and Potash, in large or small quantities, and either solid or in solution, at ROBERT RUMNEY'S, Ardwick Chemical Works, Manchester.

Silicates of Soda and Potash in the state of Soluble glass, or in CONCENTRATED SOLUTION of first quality, suited for the manufacture of Soap and other purposes, supplied on best terms by W. GOSSAGE and Sons, Widnes Soper, Warrington.

London Agents, CLARKE and COSTE, 19 and 20, Water Lane, Tower Street, E.C. who hold stock ready for delivery.

THE CHEMICAL NEWS.

VOL. XXII. No. 567.

ON THE DISCRIMINATION OF FIBRES IN MIXED FABRICS.*

By JOHN SPILLER, F.C.S.

It is often a matter of importance to separate or distinguish the fibres of silk, wool, cotton, jute, &c., when interwoven, or composing the structure of mixed fabrics, and much progress has been made towards the identification of such fibres by the close examination of them under the microscope. With the view of aiding such enquiries, I beg leave to point attention to some new chemical tests, by means of which the character of the component fibres in mixed goods may be very readily determined. At the outset, I may state that there are many processes of examination which are already known to, and employed by, practical dyers, such methods usually depending upon the comparative facility with which certain colouring matters are taken out of a dye-bath, by virtue of special affinities exerted between one or other of the component fibres and the dyes exhibited; thus it is well known that indigo, and soluble blues and violets of the aniline series, attach themselves to wool much more freely than to cotton, whilst safflower and regina have a decided affinity for cotton.† The nitric acid test for wool is also well known and often applied, but the use of dilute alkalis for dissolving out wool from silk and cotton has never, in my hands, given satisfactory results.

I proceed at once to indicate the test upon which I rely for the identification of silk when mixed with any other animal or vegetable fibres, which test can, of course, be applied to the detection of inferior staple in a supposed pure silk. The reagent employed is concentrated hydrochloric acid, which I find has the property of dissolving silk immediately and completely, without appreciably affecting any woollen or lignine fibres (cotton, linen, jute, &c.) with which the silk may have been interwoven. Strong sulphuric acid has also a powerful solvent action upon silk, but its effect upon cotton is much more destructive than in the case of hydrochloric acid. The use of these acids for the purpose of testing the quality of silk has been frequently resorted to by my friend, Mr. James Kayess, of the Garratt Print Works, near London, and myself during the past three years, and, in conjunction with the gentleman I have named, the original experiments were made upon which the efficacy of this method of testing silk was clearly established.

Having, then, submitted the material to the action of hydrochloric acid, and noted any indications of rupture or solution of the fibres, the residual fabric or loose filaments may now be washed and collected, and will usually be destitute of colour. We have next to determine the presence or absence of wool in that portion of the fabric which resists the attack of hydrochloric acid; and, for this purpose, I know of no better test than the use of picric acid, as recommended by Professor Pohl, of Vienna, and fully described in Watts's "Dictionary of Chemistry," vol. v., p. 1047. A warm aqueous solution of picric acid instantly imparts a full yellow tint to wool, but does not in the least affect cotton, linen, jute, or China grass, so that it is only necessary to immerse the fabric or fibres in the dye, wring out, and wash well with water in order to remove the adhering yellow solution, and note any indications of the existence of wool. I have

ascertained that cotton may be so treated without retaining any trace of the colour, and that a previous digestion in hydrochloric acid in no way affects the result. In the examination of ribbons, and some other stiffened goods, it is often necessary to immerse them for a few minutes in boiling water, to dissolve out the starch or size prior to applying the hydrochloric acid test, for, by this simple expedient, the results are rendered much more decisive.

The above will be deemed the readiest mode of proceeding, but it will be well to mention other methods of distinguishing between wool and cotton. We can use, for instance, an acidulated solution of Hofmann violet or of soluble blue; iodine green may be employed, or, lastly, the Nicholson blue, which, applied in alkaline solution, is much more readily taken up by wool than by cotton. As means of confirmation, the use of any one of these dyes may be resorted to, and a direct comparison instituted, if necessary, with known materials.

By the system of examination just now described, I have examined a large series of mixed fabrics and coloured goods, without observing any difficulty in the detection of the silk and wool entering into the constitution of such materials. With respect to the identification of the fibres which remain unaltered by this treatment—the discrimination of cotton from flax, for instance—I have hitherto relied upon their structural peculiarities as indicated more conspicuously by the microscope, and this part of the subject has, besides, been fully treated of by Mr. W. T. Suffolk, in his recent work, entitled "Microscopical Manipulation."

By way of conclusion, I append a short description of the chemical properties of the solution obtained by acting upon silk with hydrochloric acid. The mucilaginous liquid so prepared cannot be evaporated, even over a water-bath, without becoming somewhat carbonised; the free acid may be partially separated by dialysis, or by exposure to air in a shallow capsule, placed within a bell-jar charged with a liberal supply of slaked lime to absorb the hydrochloric fumes, but the resulting solution will not then bear dilution with water without precipitation of the animal matter. Ammonia, added in excess, forms a clear solution, which I am hopeful of being able to employ in photography, for when this liquid is evaporated there is left a brown saline residue of rough astringent flavour, which, when mixed with aqueous nitrate of silver, gives a peculiar flocculent form of argentic chloride, which is no longer curdy, and much more rapidly affected by light than the ordinary condition of chloride of silver. These properties enable the silk-compound to be usefully employed in the production of "matt-paper" prints and direct solar-camera enlargements. Its application to the collodion-chloride process appears also to be worthy of trial.

When caustic soda in excess is added to the silk-solution, and afterwards a small proportion of the sulphate, or, better, the sodio-tartrate, of copper, a fine purple colouration is observed, which is permanent, and seems to afford a characteristic indication of the nature of the animal substance dissolved. No red cuprous oxide is thrown down upon boiling this solution. A white precipitate is formed when the solution of silk is neutralised with a caustic or carbonated alkali, and the product exhibits a considerable affinity for dyes, as does also the mixed substance resulting from the addition of an acid solution of silk to an alkaline solution of wool. In the latter case, however, the evolution of sulphuretted hydrogen will be noticed as an unfavourable feature of the reaction, and probably indicates the breaking up of the constitution of the wool. The brownish uncrystallisable residue left upon evaporation of the pure silk-solution reads strongly acid to test-papers, and has, whilst warm, an odour suggestive of caranell; when strongly heated, it burns with a brilliant flame, giving off the well-known odour of singed hair or feathers, like many other nitrogenous animal substances. The preparation of the new silk-compound on a large scale, and in the state of purity, has

* Read before the British Association, Liverpool Meeting, Section B.

† The new "Spiller purple" likewise shares the property here referred to, going well upon cotton without any mordant.

hitherto presented difficulties on account of the peculiar nature of its properties, and the liability to become charred in the process of evaporation.

ON THE
SEPARATION OF PHOSPHORIC ACID FROM
IRON ORES AND IRON CINDERS.*

By JAMES HARGREAVES.

I NEED not here enter into any lengthened description of the evil effects of phosphorus upon iron; suffice it to say that iron containing phosphorus in appreciable quantities is utterly unfitted for the manufacture of steel, and is considerably deteriorated whether it is used in the form of cast or malleable iron. Hence it is desirable to get rid of the phosphorus to prevent this deterioration.

This subject had to some extent attracted my attention for several years, but not so far as to make it a matter of especial study and experiment, but, about five years ago, my attention was more closely drawn to the subject, and I proposed the use of alkaline nitrates as a means of converting cast-iron into steel, and, at the same time, separating any phosphorus that might be present. By the use of nitrate of soda I have found it to be quite practicable to produce a good serviceable steel direct from phosphoric pig.

The process, however, was not carried out on a real working scale, for reasons entirely apart from its technical merits, to explain which would be to go into personal matters, which are quite foreign to the objects of this association. But while engaged in the attempt to develop this steel process, the fact forced itself upon my attention that phosphorus had hitherto been too much looked upon as something to be *got rid of*, and not sufficiently as something to be *got hold of*; and that to effect the latter would be the best means of effecting the former. It was talked of and regarded by the iron manufacturers as "dirt," but that was because it was "matter in the wrong place," and the only way to make it cease to be dirt was to put it in the right one. I felt this to be a matter of considerable importance, and have often pressed as a subject of study by my fellow chemists, some commercially practical means of obtaining the phosphorus either alone or in some of its available compounds. I pointed this out in a paper read before the Liverpool Polytechnic Society in November, 1867, and again before the Cleveland Institute of Engineers, at Stockton-on-Tees, in March, 1868. But at the latter place I was simply ridiculed for even alluding to anything so very preposterous, the very fact that there was such an immense amount of phosphoric ores consumed being quoted as a reason why the proposal should be considered impracticable. I refer those who are interested in this subject to the *Engineer* for the earlier part of 1868, for copies of the papers read at Liverpool and Stockton.

It seems, however, that no one has, so far as I can learn, thought proper to give this subject the attention which it deserves—not even those who are most interested in it, and whose opportunities and inducements must be very much greater than my own. In fact, it has almost seemed as if those who would naturally be expected to take the greatest interest in the subject are the last to pay any attention to it. It is one which I was anxious to see carried into practical operation, no matter by whom, as I looked, and still look, upon it as a question of not only pecuniary, but what is immeasurably greater, of vital importance, one affecting health and life, for, in the absence of phosphates, no bony frames can be formed to cover with muscles and endow with vital force; and one of the limits which bound the existence of man and the lower animals is the quantity of phosphoric acid which

can be made available and used as a vital "circulating medium."

I need not dilate upon the importance of a large and practically exhaustless source of phosphoric acid, especially so long as our municipal authorities continue to make use of our streams as convenient conveyances to deposit our supplies of phosphates in the sea, instead of using the sewage to re-fertilise the soil which has been exhausted in the production of food. Seeing this waste (which is nothing less than criminal) one would imagine that we did not expect to be followed by future generations, or else that some one had invented some improvement on the work of the Omnipotent, and the framework of the bodies of future generations were to be built up without the use of phosphates at all. By proper utilisation and conservation of the elements of food, whether in the form of excretal matters or of mineral substances, it is possible that to make "every rood of ground maintain its man" may be not only the aspiration of a poet, but a matter of sober fact.

As an illustration of the quantity of phosphorus which is present in the iron made in Great Britain, I may point to Cleveland, which manufactures $1\frac{1}{2}$ millions of tons of iron per annum. This iron, at the low estimate of $1\frac{1}{2}$ per cent, contains 18,750 tons of phosphorus, which is equal to 42,943 tons of phosphoric acid. This phosphoric acid is sufficient to supply the phosphoric constituents to 3,400,000 tons of wheat. In the absence of strict statistics on the subject, it is not too much to assume that, in the whole of the British iron manufacture, this quantity might be tripled, with every confidence that it is considerably under rather than over the fact.

When phosphoric pig-iron is converted into malleable iron, the phosphorus is, in great part, transferred to the refinery and puddling furnace cinder in the form of phosphate of iron. The quantity of phosphoric acid varies of course with the composition of the pig-iron from which it is contained. The cinder produced from refining and puddling Cleveland pig contains generally from 3 to 7 per cent of phosphoric acid, which is from one-fourth to one-half the phosphoric acid present in good commercial soluble phosphate of lime. This cinder is sometimes again used for the manufacture of pig-iron, but the product is, on account of the accumulation of phosphorus, of small commercial value, while, if the phosphoric acid were previously separated, it would be capable of yielding iron quite equal to that produced from hematite, or could be again used for "fettling" puddling furnaces.

While at this part of the subject I may refer to the contradictory and incoherent theories given to account for the separation of phosphorus from the iron and its transference to the cinder while being converted into malleable iron by the ordinary refining and puddling processes, while in the Bessemer process the amount of phosphorus separated is very small. I could get no satisfactory explanation from other sources, and, therefore, made these reactions a subject of study and experiment for over three years, and I gave the results in a paper read before the Liverpool Polytechnic Society. To repeat this would extend this paper to too great length, and I must refer those who take an interest in the subject to the *Journal of the Society* for May, 1869.

The concentration of the phosphorus from the pig into the cinder in the form of phosphate of iron renders it more easy and practicable to separate when the preparation of compounds of phosphoric acid is the object in view, as there is a smaller bulk of material to be treated to obtain a given amount of product.

The phosphoric acid may be separated either in the form of soluble superphosphates of lime and magnesia or of the alkaline tribasic phosphates. To effect the former the cinder is melted with lime and magnesia; and to do this it is best to either use lime in the furnace during puddling, or else add it at the end of the operation before the cinder is run out, so as to save the fuel required to re-melt it. This is then roasted in the ordinary way of

* Read before the British Association, Liverpool Meeting, Section B.

making what is technically called "bull-dog." By this roasting the protoxide of iron is converted into magnetic oxide or into peroxide of iron, both of which are very slowly soluble in cold dilute hydrochloric acid, while the phosphate of lime is readily dissolved out, leaving the oxide of iron and silica behind. Or, instead of fusing the cinder with lime, it is first dissolved in hydrochloric acid, the silica being left behind insoluble, except a small proportion of gelatinous silica; sufficient lime or chloride of calcium is added to saturate the whole of the phosphoric acid present in the cinder. The chloride of iron is then concentrated to dryness. If in an open reverberatory furnace and in an atmosphere containing water vapour, hydrochloric acid is again liberated, which can be condensed and used again to dissolve more cinder. The peroxide of iron is then heated to redness to render it insoluble, and cold dilute hydrochloric acid added, which dissolves out the phosphate of lime, leaving the oxide of iron nearly pure. If it is desirable to obtain the chlorine in its isolated state instead of in the form of hydrochloric acid, the chloride of iron is dried in a close vessel, and dry atmospheric air passed through it at a temperature about the melting-point of zinc; the chlorine is liberated and peroxide of iron formed. The manufacture of chloride of lime or bleaching-powder can, therefore, be economically carried on in connection with the manufacture of phosphates and pure iron oxide, dispensing with the use of manganese, and with the further advantage that a given amount of hydrochloric acid will produce double the amount of chlorine that can be produced by the use of manganese. To obtain phosphate of soda, I keep the cinder free from lime and grind it to a powder, then I add a solution of caustic soda in good excess, so as to separate the whole of the phosphoric acid from the cinder before throwing the cinder out, and add the solution of phosphate and excess of caustic soda from that to an excess of cinder, so as to convert the whole of the caustic soda into phosphate. The partially exhausted cinder is then again treated with an excess of caustic soda to separate the whole of the phosphoric acid. The diphosphated cinder still contains the silica originally present, and it seems to combine with some of the soda used to dissolve out the phosphoric acid, as there is often 20 per cent of the soda used remaining in the cinder. This cinder may be again used to fettle puddling furnaces, and the soda present in it cannot but facilitate the transformation of the phosphorus in the pig into phosphoric acid in the cinder; the presence of the silica, however, is objectionable, on account of its neutralising a great proportion of the bases present in the cinder. It is desirable that the cinder produced from the fettling and the iron together should be as free as possible from anything which can saturate the basic material, so as to allow of a greater amount of free base, which readily facilitates the formation of phosphate of iron. To allow of this when making phosphate of soda, I dissolve the cinder the same as before mentioned, leaving the insoluble silica behind. The chloride of iron is then dried and used in the production of chlorine, or the hydrochloric acid may be again recovered to use over again. The oxide of iron, plus phosphate of iron obtained after the separation of the chlorine, is then treated with caustic soda to obtain solution of phosphate of soda, the practically pure oxide of iron remaining insoluble. The phosphoric acid in the iron ores exists principally as phosphate of lime, which, in fact, is the remains of extinct animals. To separate the phosphate, the ore is roasted so as to render the oxide of iron insoluble. The ore is broken into suitable sized pieces, say about 2 inches cube, and cold dilute hydrochloric acid run through it, which takes up the phosphate into solution, leaving the oxide behind.

The limit to the manufacture of the acid phosphate is, practically, the quantity of hydrochloric acid which is produced in the manufacture of sulphate of soda, over and above what is required for the manufacture of bleaching-powder and a few other purposes. The exact quantity

of this acid I have not had time to ascertain with any degree of accuracy, but in the alkali works on the Mersey, and it is much the same in other places, there are literally brooks of hydrochloric acid run to waste; besides, the fact that the acid at present used in the manufacture of bleaching-powder can, by the use of chloride of iron process, be reduced to one-half and, in many cases, to less than one-third, its present quantity, will liberate a still further supply of acid to be used in the preparation of acid phosphates. There is here an opening for the consumption of a great amount of valuable material which is at present run to waste. There is, of course, no practical limit to the further production of hydrochloric acid, whatever may be the quantity required, if a rise in price should occur sufficient to justify its special manufacture, and the manufacture of phosphate of soda is also unrestricted so far as supplies of soda are concerned.

The only objection to the use of such hydrochloric acid as is produced in the course of the alkali manufacture is the presence of arsenic. This, however, is practically a small difficulty, the same person who produces the hydrochloric acid also produces sulphide of calcium in the shape of alkali waste. A current of sulphide of hydrogen (which can easily be produced from the waste) passed through the acid readily precipitates the arsenic in the form of orpiment, for which there is a regular demand at remunerative prices. The separation of the arsenic will, if fairly obtained, more than pay for the cost of obtaining it.

ON MARBLES FROM THE ISLAND OF TYREE.*

By EDWARD C. C. STANFORD, F.C.S.

TYREE is one of the few islands in the Hebrides where limestones are found, and two varieties are sufficiently remarkable to form the subject of this note. Both occur at Balephetrish, on the north-west side of the island, and near the coast. One of these occurs as a beautiful pink marble with dark green spots, and this, I believe, is unknown in any other part of the world.

The pink colour is due to peroxide of iron, and the dark green spots, which vary in quantity considerably in different specimens, are crystals of horn-blende. Three selected specimens accompanying this paper illustrate this variety. It takes a good polish, and two small polished pillars of it may be seen in the British Museum. There is difficulty, however, in procuring large slabs, as these generally contain some pieces of horn-blende, several inches in diameter and difficult to polish. It is a beautiful marble for inlaying in small pieces; its effect is well shown inlaid in a fine white marble mantelpiece in Inverary Castle. The white marble is too hard for ordinary working, but, as a facing-stone for exterior work, it would be almost imperishable.

The proportion of magnesium is remarkable.

The horn-blende in the pink, and the silica in the white, are variable.

	Pink.	White.
Calcium carbonate	70·85	50·70
Calcium sulphate	trace	—
Magnesium carbonate	2·35	37·92
Peroxide of iron	3·40	—
Calcium phosphate	—	0·80
Silica	—	10·18
Horn-blende	23·40	—
Water	—	0·40
	100·00	100·00

The peroxide of iron is scarcely soluble in dilute hydrochloric acid, which leaves most of the colouring matter.

* Read before the British Association, Liverpool Meeting, Section B

ON THE
EXISTENCE OF TWO SPECTRA PRODUCED BY
CARBON INCANDESCENT AT THE SAME
TEMPERATURE.*

By W. MARSHALL WATTS, D.Sc.,
Physical Science Master in the Manchester Grammar School.

ONE of the most interesting questions in the present stage of spectral analysis is the cause of the differences which are observed in the spectra of certain elements. The changes which can be brought about in the spectrum of a substance, by altering the conditions under which it is produced are of three kinds:—

(1). Simple addition of new lines—for example, the addition of the blue line to the lithium spectrum when the electric light is employed instead of the flame.

(2). Replacement of bands by groups of well-defined lines possessing generally nearly the same refrangibility—for example, the changes which take place in the spectra of strontium and calcium when they are produced by the electric spark instead of the flame.

(3). Total alteration of the spectrum—for example, the primary and secondary spectra of nitrogen, as described by Plücker and Hittorf.

There can be no doubt that changes of the first class are due simply to change of temperature; that is to say, at the higher temperature other atomic vibrations are set up simultaneously with the vibrations to which the lines of the lower temperature are due.

Changes of the second class are probably due to chemical decomposition. Thus, the broad bands of the calcium spectrum observed at the lower temperature of the flame are probably produced by the glowing vapour of calcium oxide; whereas, at the high temperature of the intense electric spark, the oxide is decomposed, and the metal vapour gives the fine lines which take the place of the bands.

Changes of the third class are more difficult of explanation.

They have been observed by Plücker and Hittorf, in the case of hydrogen, nitrogen, sulphur, selenium, phosphorus, and iodine; and by Wüllner, in the case of hydrogen, oxygen, and nitrogen. Wüllner has recently shown that hydrogen is capable of giving at least four different spectra. These different spectra of hydrogen are all obtained by the use of electricity; and both Plücker and Wüllner believe the changes to be caused by change of temperature. Thus Plücker says—"There is a certain number of elementary substances which, when differently heated, furnish two kinds of spectra not having any line or any band in common;" and Wüllner writes—"The difference of temperature must, in the case of hydrogen, be regarded as the sole cause of this phenomenon, for a decomposition into further elements is not to be thought of."

Carbon exhibits changes of spectrum, not only of the first and second classes but also of the third. I believe that I have obtained evidence that two of these spectra are produced at the same temperature.

Firstly, as to the evidence that each of these spectra is actually the spectrum of carbon itself, and not of any compound of carbon. The first of these spectra is shown to be that of carbon, inasmuch as it is common to olefiant gas, cyanogen, and carbonic oxide. It can be obtained from any one of these gases, by passing the electric spark through it, but is obtained most brilliantly by burning olefiant gas (or cyanogen) with oxygen in an oxyhydrogen jet. The second spectrum is shown to be that of carbon, inasmuch as it can be obtained alike from carbonic oxide, olefiant gas, or carbonic disulphide, and is most easily obtained from a Geissler's tube enclosing coal-gas.

The temperature of the first carbon spectrum is obtained with a certain degree of accuracy from the temperature of flames which give it.

The temperature of any flame can be calculated on the assumption that the whole heat of combustion is expended in raising the temperature of the products of combustion. The calculated temperature of a flame can never be less than the actual temperature, but is, in many cases, considerably too high, in consequence, principally, of dissociation; but the calculated temperatures are generally less in error when the combustion takes place in air, than when it takes place in oxygen. This will be seen from the following comparison of the results of calculation with the experimental results in those few cases in which trustworthy experimental results have been obtained:—

Combustion in Oxygen.			
	Calculated flame temperature.		Experimental.
	°C.		°C.
Hydrogen	6880		2844
Carbonic oxide	7067		3033
Combustion in Air.			
	Calculated.		Experimental.
	°C.		°C.
Hydrogen	2738		2024
Carbonic oxide	2996		1997
Cyanogen	3519		3297

The first carbon spectrum is obtained from the flame of olefiant gas in air, the calculated temperature of which is only 2619° C. No experimental determination of this temperature has been made. It is also obtained from the flame of a mixture of cyanogen and carbonic acid, the calculated temperature of which is 2016°; and can also be obtained from the inner blue cone of a Bunsen flame, the temperature of which is shown to be less than 2000° C., because, although it is capable of melting a fine gold wire (fusing-point 1300° C.), it refuses to melt the finest platinum wire (fusing-point 2000° C.).

The same spectrum (with the addition of some lines) is obtained from the flame of cyanogen in air, the temperature of which is determined, by calculation, to be 3519° C., and by experiment, 3297°. It is also obtained from the flame of cyanogen in oxygen, the calculated temperature of which is 10,557° C. We may therefore conclude that this spectrum is produced at any rate between the temperatures of 2000° C. and 3000° C.

The second carbon spectrum is obtained only by the use of electricity, and the difficulty of measuring the temperature of the ignited gas is great. I have sought to overcome this difficulty, by including sodium vapour with the gas in the Geissler's tube. We can hardly refuse to admit that the temperature of the ignited sodium vapour must be the same as that of the carbon compound; and the sodium spectrum contains certain lines, visible only at high temperatures, from which the temperature can be determined.

If the temperature to which the sodium vapour be heated be sufficiently high, the spectrum contains, besides the well-known double line, four other lines, each of them double; I denote these lines as Naβ, Naγ, Naδ, and Naε. In the Bunsen flame, the D lines only are obtained; but, if the temperature of the flame be increased, these other sodium lines come out one by one, and in the order given above. I find that Naβ becomes visible almost precisely at the temperature at which platinum melts—that is, 2000° C.; so that, if a bead of sodium carbonate be brought into any flame incapable of fusing platinum, only the D lines will be seen, but, if the flame be hot enough to fuse platinum, Naβ will also be visible.

For example—

The Bunsen flame gives the D lines only, and is incapable of fusing platinum.

The flame of coal-gas, fed by a jet of air mixed with a little oxygen, gave Naβ, but not Naγ. The flame fused platinum easily.

The flame of carbonic oxide in air (temperature, 1997° C.) gave only D; it is incapable of fusing platinum. Carbonic oxide fed by oxygen (temperature 3033° C.) gives Naβ and Naγ.

* Read before the British Association, Liverpool Meeting, Section A.

We conclude, therefore, that Na β indicates a temperature of at least 2000° C., and that Nay comes out about 3000° C.

If now the discharge of an induction coil be passed through a Geissler's tube containing carbonic oxide and sodium, the carbon spectrum No. 2 is obtained; and if the sodium be volatilised, the sodium lines come out one by one as the tube gets hot, and the carbon lines are seen simultaneously with Na β , and (at first) without Nay. Hence we conclude that this second spectrum is also produced by carbon between the temperatures of 2000° and 3000° C. I do not presume to attempt an explanation of this difference of vibration at the same temperature. In view of the fact that the second spectrum is produced only by means of electricity, the question suggests itself—Whether the atomic vibrations of the gas produced by the electric discharge are different in kind from the vibrations which we measure as temperature? Or, if a very crude hypothesis may be allowed, I would suggest that identity of temperature means identity of molecular vibration, but that the light emitted is caused by the inter-molecular vibration of atoms. If this hypothesis be admitted, a test experiment suggests itself. If, by increase of temperature, the velocity of the molecules of a gas be increased, the refrangibility of the light, caused by the vibrations of their constituent atoms, ought to be slightly increased in the motion of the molecule towards the observer, and slightly diminished in the motion of the molecule from the observer; so that a line ought to become broader when the temperature of the source of light is increased.

If, then, the slit of a spectroscopic be partly illuminated with sodium-light from a flame of low temperature, and partly from the intense electric spark, the D lines should exhibit a less interval in the latter case than in the former. A rough calculation shows that, if the temperature of the flame be 2000° C., and of the spark 10,000° C., the interval between the two sodium lines ought to be diminished by about one-twentieth. I have endeavoured to detect this difference, but the dispersive power of the spectroscopic at my disposal (a three-prism instrument, kindly lent by my friend Mr. S. Okell) was not great enough.

ANALYSIS OF SOME HITHERTO UNDETERMINED AMERICAN MINERALS.

By Professor LEEDS.

I.

A GREENISH-WHITE, translucent, compact mineral, from Van Arsdale's quarry, near Attleboro', Bucks County, Pennsylvania, previously regarded as Ekebergite.

Percentage Composition.

Sp. gr., 271.		
SiO ₂		47.47
Al ₂ O ₃		27.51
Fe ₂ O ₃		trace
MgO		1.20
CaO		17.59
Na ₂ O		3.05
K ₂ O		1.40
H ₂ O		1.48

99.70

The atomic ratio, obtained by multiplying the quotients of these per cents by the atomic weights into the quantities of the radicals, is—

Si		0.790 × 4 = 3.16		3.16 or 12.
[Al ₂]		0.270 × 6 = 1.62		1.62 or 6.
Mg		0.030 × 2 = 0.06		—
Ca		0.310 × 2 = 0.62		—
Na ₂		0.050 × 2 = 0.10		—
K ₂		0.015 × 2 = 0.03		—
H ₂		0.080 × 2 = 0.16		0.97 or 4.

Excluding the percentage of water, as has been done hitherto in the computation of the formulæ of these and analogous silicates, we have for the atomic ratio, 1 : 2 : 4. If we deduct the amount of Si corresponding to the H₂, regarding the matter as existing in the mineral in the form of hydrate of silicic acid, we again have the ratio 4 : 6 : 12, and the formula (Ca,Na₂)₂[Al₂]Si₃O₁₀. And the mineral is Scapolite.

The same mineral is found in the locality mentioned above, in imperfect crystals with rough faces. It is associated with pyroxene, graphite, sphene, and phlogopite in granular limestone.

II.

A variety of orthoclase, which is described by I. Lea* as being of a dull bluish-green colour, and semi-transparent, with very minute crystalline hexagonal plates disseminated through the mass, and giving out very bright reflections. These plates may be seen with the naked eye. The name proposed for this variety was *cassinite*. It is found in a ploughed field on a serpentine ridge known as Blue Hill, in Upper Providence Township, Delaware County, four miles north-west of Media.

Percentage Composition.

SiO ₂		64.20
Al ₂ O ₃		19.69
Fe ₂ O ₃		0.69
CaO		2.27
MgO		0.15
K ₂ O		9.59
Na ₂ O		3.43
H ₂ O		0.27

100.29

Its formula is (K₂,Na₂)[Al₂]Si₆O₁₆, the same as common orthoclase.

III.

A yellowish white mineral, with rhombohedral cleavage and vitreous lustre, occurring imbedded in steatite. It is associated with a ferruginous dolomite, and often intermixed with it: becomes brown on exposure. It is found at the soapstone quarry on the north-east bank of the Schuylkill river, on the line between Philadelphia and Montgomery County.

Percentage Composition as given by the Mean of Two Analyses.

MgO		38.43
FeO		10.39
CaO		3.29
CO ₂		47.90

100.07

It is to be regarded, therefore, as a ferriferous magnesite, or breunerite.

My thanks are due to Mr. Theodore D. Rand, who obtained the specimens of these three minerals at the localities, and kindly presented them to me for analysis.—*Journal of the Franklin Institute.*

ON THE NUMBER OF ISOMERIC BODIES.†

By O. LOEW.

THE rational formulæ of organic combinations differ so much among themselves at the present time, and are occasionally so incomprehensible, and on no reasonable ground, that it is of the greatest importance to organic chemistry when a man of Kolbe's learning undertakes to reconstruct the rational formulæ on as natural a basis as possible, and in correspondence with the true characters of bodies.

* *Proceedings of the Academy of Natural Sciences of Philadelphia*, 1866.

† Communicated by the Author.

The chief feature in Kolbe's theory is substitution, whereas other chemists, under the lead of Kekulé, follow that of agglomeration, and of the so-called binding and linking of the atoms.

Taking an unprejudiced view of Kolbe's formulæ, it will be observed that they express all the decompositions which the body under consideration undergoes by means of different reagents, and that no other formulæ can explain the nature and the number of the isomerism, which are at times very numerous.

Considering, by way of example, the so-called ether radicals—

methyl = $\begin{matrix} \text{H} \\ | \\ \text{H} \end{matrix} \text{C}$ and ethyl $\begin{matrix} (\text{H}_3\text{C}) \\ | \\ \text{H} \end{matrix} \text{C}$ have no mono-

carbolic isomerism; but when we take the next highest radical, "propyl," we find two isomerism, which are represented by the following rational formulæ—

No. 1 is the true homologue of methyl; No. 2 is the so-called isopropyl, a secondary radical, yielding no respective aldehyd.

Passing now to butyl, C_4H_9 , when we define it is a derivative of methyl, in which hydrogen is substituted for methyl, ethyl, or propyl, we find already four isomerism.

True homologue.

Second primary radical.

Secondary radical.

Tertiary radical.

The next highest radical is amyl, C_5H_{11} , in which we find already eight isomeric monocarbolic radicals, namely, four primary, three secondary, and one tertiary. Adding all these monocarbolic and bicarbolic radicals, which are isomeric to amyl, we obtain a much higher number (*vide* Table).

The monocarbolic radicals of the formula of capryl show seventeen isomerism. In this manner we obtain:

for septyl, C_7H_{15} = 39 isomerism,
for octyl, C_8H_{17} = 89 "
for nonyl, C_9H_{19} = 221 "
for decyl, $\text{C}_{10}\text{H}_{21}$ = 619 "
&c.

The general rule from capryl up is expressed thus: that for a body of the general formula $\text{C}_x\text{H}_{2x+1}$, there exist more than $2^{(x-2)}$ isomeric monocarbolic combinations, and less than $2^{(x-1)}$. If we apply this law upon stearic acid = $(\text{C}_{17}\text{H}_{35})[\text{CO}]\text{OH}$, we find there exist more than 2^{15} = more than 131072 isomerism.

The different stearic acids are probably very difficult to distinguish, even by means of polarised light, or by the melting point, but we cannot deny the possibility that at some future time we may be able to construct more delicate and subtle instruments to separate bodies, which, although only isomeric, do not show a striking chemical difference. An example illustrating these remarks very satisfactorily is shown by the oil of turpentine, $\text{C}_{10}\text{H}_{16}$.

We know a great number of hydrocarbons which have this formula—for instance, oil of lemons, of cubebs, of juniper, &c. The great difference in the smell leads us to the conclusion that there must be a difference in their chemical constitution. There are several other hydrocarbons of the formula $\text{C}_{10}\text{H}_{16}$ which show no difference in smell, although they differ from oil of turpentine in the

power of turning the plane of polarisation; which is the fact that shows us that these bodies are not identical, but are isomeric.

Kolbe considers the oil of turpentine as a dicarbolic. Dicarbol is hydrocarbons in which two atoms of the same hydrocarbon are connected by a diatomic radical. According to Kolbe, benzol is a tricarbolic.

Kolbe, in his theory, points out the analogy between tricarbols and triamins, the latter of which are known as bodies of a well-defined constitution. The ingenious theory of Kolbe has, consequently, a true and positive foundation.

We will now calculate how many isomerism exist in the derivatives of ammonia; in a manner similar to the above, we find for—

- | | | |
|-------------------|--------------|-----------------------------|
| (1.) Ethylamine, | 2 isomerism. | (1 primary, 1 secondary.) |
| (2.) Propylamine, | 4 " | (2 prim., 1 sec., 1 ter.) |
| (3.) Butylamine, | 8 " | (4 prim., 3 sec., 1 ter.) |
| (4.) Amylamine, | 17 " | (8 prim., 6 sec., 3 ter.) |
| (5.) Caprylamine, | 39 " | (17 prim., 15 sec., 7 ter.) |

These numbers are only calculated for the monocarbols contained in these bases. The general law is thus:—

For a base of the general formula—

there exist more than $2^{(x-1)}$, and less than 2^x isomerism.

If now we wish to see how many isomerism exist in the non-saturated hydrocarbons, in the oxy-amido-nitro products, we would be obliged to calculate an immense number of bodies. This example shows sufficiently how fruitful Kolbe's theory is, how the numerous isomerism may be explained, and what a prospect Kolbe opens for the existence of an immense number of bodies.

Isomerism of Amyl. C_5H_{11} .

I. Monocarbolic Radicals.

a. Primary. (4.)

True Homologon to Methyl.

b. Secondary. (3.)

c. Tertiary. (1.)

Isomerism of Amyl. C_5H_{11} .

II. Dicarbolic Radicals.

a. Primary. (2.)

b. Secondary. (3.)

Secondary dicarbolic of the first order.

Secondary dicarbolic of the second order.

IV. Tetracarboic Radical.

NOTE ON THE SPECTRA OF ERBIA AND SOME OTHER EARTHS.*

By WILLIAM HUGGINS, LL.D., F.R.S.

BAHR and Bunsen have shown† that erbium, rendered incandescent in a Bunsen's gas-flame, gives a spectrum of bright lines in addition to a brilliant continuous spectrum. As they were unable to discover the bright lines in the flame beyond the limits of the solid erbium, they suggest that the light which is dispersed by the prism into bright lines is emitted by the solid erbium, which substance therefore appears to stand alone, as a remarkable exception, among solid bodies. Bahr and Bunsen found the spectrum of bright lines to coincide very nearly with the absorption spectrum of some compounds of erbium.

A few weeks since, when in Ireland, I made the observation that the spectrum of the ordinary lime-light contains bright lines.‡ Dr. Emerson Reynolds, Director of the Laboratory of the Royal Dublin Society, kindly undertook to make experiments to ascertain from the position of the lines if they were due to the cylinder of lime, or to impurities contained in it.

Upon my return to town I made the following experiments; shortly after commencing them I received from Dr. Reynolds the account of his experiments, which, with his permission, I have added to this note.

Erbium.—A few months since I received, through the kindness of Dr. Roscoe, F.R.S., a few grains of nitrate of erbium, which he had procured from a trustworthy source. I followed Bunsen's method of placing it with syrupy phosphoric acid upon a platinum wire. The erbium, obtained by this method in a finely divided state, was then submitted to the heat of the oxyhydrogen blowpipe.

In all the experiments described in this paper hydrogen alone was first turned on, and the effect of the heat of the flame on the substance under examination observed with the spectroscopist. Oxygen was then admitted slowly, and the effect of the increased heat carefully noted.

With the flame of hydrogen alone, the lines represented in the map which accompanies Bahr and Bunsen's paper were seen, but the lines were more distinct when a small proportion of oxygen was admitted. With the full proportion of oxygen, the light from the glowing erbium was more intense, but the lines were not so well seen. Even with the intense heat of the oxyhydrogen flame I was unable to trace the lines beyond the limits of the solid erbium, though the line of sodium could be seen for some distance from the erbium. I found, however, that the lines appeared more distinct, in consequence, probably, of their being brighter relatively to the parts of the continuous spectrum where they occur, when the slit was directed from the side upon the gas immediately in front of the glowing part of the erbium.

The spectrum of bright lines obtained by means of the oxyhydrogen flame agreed more completely with the absorption spectrum represented by Bahr and Bunsen

(No 2 in their diagram) than the spectrum of bright lines figured by those observers (No. 3). The most important differences occurred in the band in the red, which showed two points of greatest brightness, thus forming a double line with a little outstanding light, and the line at the green at 65 of the scale, which was double, precisely as the corresponding absorption-line is represented in spectrum No. 2 of the diagram.

Lime.—The experiments were made with the cylinders of lime prepared for use with the oxyhydrogen blowpipe, and also with pieces of pure caustic lime, but there was no sensible difference presented in the spectroscopist.

The bright lines consisted of a double line in the green, and several bands in the orange and red, which were found to form a spectrum identical with that which is produced when chloride of calcium is heated in the flame of a Bunsen's burner.

When the spectroscopist was directed to a point in the flame a little above the incandescent portion of the lime, the lines appeared beyond the bright continuous spectrum, showing that they are not produced by the white-hot solid lime, but by the luminous vapour into which a portion of the lime has been converted by the heat of the flame.

Magnesia.—The commercial heavy oxide of magnesium was made into a paste with distilled water, and formed into a small pellet upon the end of a platinum wire. The pellet of magnesia was slowly dried, and then placed in the oxyhydrogen flame. I was surprised to see a spectrum of bright lines precisely similar to that which is produced by lime. Chloride of magnesium, when introduced into the Bunsen flame, gave a similar spectrum. I record these results as the oxide and chloride were those sold as pure. I found afterwards that a very small trace of lime may be detected in magnesia by means of the oxyhydrogen flame.

I then took metallic magnesium, which I had found by the spectroscopist to be nearly pure, and formed from it magnesia and chloride of magnesium.

When this magnesia, formed into a small ball upon a wire, was subjected to the oxyhydrogen flame, two bright bands were seen in the green. One of these was found to be coincident with the triple line of Fraunhofer's *b*, which distinguishes magnesium, and the other with a group of bright lines which is seen between *b* and *F*, nearly in the position of the brightest double line of nitrogen, when metallic magnesium is burnt in air.

The chloride formed from magnesium, when introduced into the Bunsen flame, gave the same bands, but the more refrangible band was exceedingly faint.

When an induction-spark was taken from a wire covered with cotton-wool soaked with a solution of the chloride, the lines at *b* and the more refrangible group were seen. If the heating-power of the spark be increased by the introduction of a Leyden jar, the band between *b* and *F* becomes scarcely distinguishable, while the lines peculiar to metallic magnesium are much more intense. When a spark is taken between electrodes of the same specimen of magnesium from which the chloride was formed, no trace of this band was detected.

Baryta.—When pure caustic baryta is subjected to the heat of the oxyhydrogen flame, a brilliant spectrum is seen identical with the well-known spectrum which presents itself when chloride of barium is heated in the Bunsen flame. Baryta furnishes a larger quantity of vapour than lime and magnesia, and therefore the lines could be traced to a greater distance from the solid baryta.

Strontia.—Pure strontia was fused into a large bead upon a platinum wire. When this bead was heated by the oxyhydrogen flame, the same spectrum of bright lines presented itself as is seen when chloride of strontium is placed in the flame of a Bunsen's burner.

Zirconia.—One of the small pellets of zirconia prepared in France for use with the oxyhydrogen blowpipe was found to give no trace of bright lines. This great fixity of zirconia as compared with lime is in agreement with the inalterability of the substance under the action of the oxyhydrogen flame.

* From the *Proceedings of the Royal Society*, No. 122, 1870.

† Liebig's *Annalen*, Bd. lxi. (1866) S. i.

‡ Dr. W. Allen Miller informs me that in 1845 he noticed a bright line in the spectrum of the diffused light of the oxyhydrogen jet reflected from a sheet of paper.

Alumina.—Pure alumina treated in the same way as the magnesia gave a continuous spectrum only, without any trace of bright lines.

Glucina.—Glucina gave a bright line in the red, which I found to be due to potassium. Glucina, therefore, appears not to form vapour of any kind under the heat of the oxyhydrogen blowpipe.

Titanic acid gave a continuous spectrum without lines.

Oxide of uranium a continuous spectrum without lines.

Tungstic acid a continuous spectrum without bright lines.

Molybdic acid a continuous spectrum without bright lines.

Silica (precipitated) a continuous spectrum without bright lines.

Oxide of cerium a continuous spectrum without bright lines.

The question presents itself as to the nature of the vapour to which the bright lines are due in the case of the earths, lime, magnesia, strontia, and baryta. Is it the oxide volatilised? or is it the vapour of the metal reduced by the heat in the presence of the hydrogen of the flame? The experiments show that the luminous vapour is the same as that produced by the exposure of the chlorides of the metals to the heat of the Bunsen gas-flame. The character common to these spectra of bands of some width, in most cases gradually shading off at the sides, is different from that which distinguishes the spectra of these metals when used as electrodes in the metallic state.*

Roscoe and Clifton have investigated the different spectra presented by calcium, strontium, and barium, and they "suggest that at the lower temperature of the flame or weak spark, the spectrum observed is produced by the glowing vapour of some compound, probably the oxide, of the difficultly reducible metal; whereas, at the enormously high temperature of the intense electric spark these compounds are split up, and thus the true spectrum of the metal is obtained. In none of the spectra of the more reducible alkaline metals (potassium, sodium, lithium) can any deviation or disappearance of the maxima of light be noticed on change of temperature."†

As the experiments recorded in this paper show that the same spectra are produced by the exposure of the oxides to the oxyhydrogen flame, Roscoe and Clifton's suggestion, that these spectra are due to the volatilisation of the compound of the metal with oxygen, is doubtless correct.

The similar character of the spectrum of the bright lines seen when erbia is rendered incandescent would seem to suggest whether this earth may not be volatile in a small degree, as is the case with lime, magnesia, and some other earths. The peculiarity, however, of the bright lines of erbia, observed by Bahr and Bunsen, that they could not be seen in the flame beyond the limits of the solid erbia, deserves attention. My own experiments to detect the lines in the Bunsen gas-flame, even when a very thin wire was used, so as to allow the erbia to attain nearly the heat of the flame, were unsuccessful. The bright line in the green appears, indeed, to rise to a very small extent beyond the continuous spectrum, but I was unable to assure myself whether this appearance might not be an effect of irradiation.

It is, perhaps, worthy of remark that the chlorides of sodium, potassium, lithium, cesium, and rubidium, give spectra of defined lines, which are not altered in character by the introduction of a Leyden jar, and which, in the case of sodium, potassium, and lithium, we know to resemble the spectra obtained when electrodes of the metals are used. Now, all these metals belong to the monad group; it appeared, therefore, interesting to observe the behaviour of the other metal belonging to this group.

Chloride of silver when introduced into the Bunsen flame gave no lines. The chloride was then mixed with alumina, which had been found to give a continuous spectrum only, and exposed to the oxyhydrogen flame, but no lines were visible. When, however, the moistened chloride was placed on cotton and subjected to the induction-spark without a jar, the true metallic spectrum was seen, as when silver electrodes are used.

The behaviour of silver, therefore, is similar to that of the other metals of the monad group. Now, the difference in basic relations which is known to exist between the oxides of the monatomic and polyatomic metals would be in accordance with the distinction which the spectro-scope shows to exist in the behaviour of the chlorides; the chlorides of the polyatomic metals would be more likely to split up in the presence of water into oxides and hydrochloric acid.

In the case of some of the oxides and chlorides, one or more of the lines appeared to agree with corresponding lines in the metallic spectra; it may be, therefore, that, under some circumstances, as in the case of magnesium burning in air, the metallic vapour and the volatilised oxide may be simultaneously present.

Dr. Reynolds's Experiments.

"After you observed the occurrence of two bright lines in the spectrum of the light emitted by incandescent lime, you recollect we identified these as belonging to calcium. At the time we supposed that these lines were produced by the ignition of the vapour of some volatile calcium compound probably present as an impurity in the sample of limes used in the experiments. If this explanation was found to be true for lime, the bright lines seen in the spectrum of erbia might possibly be accounted for in a similar manner. In order to examine the matter fully, I arranged the experiments described below.

"I selected two oxides for comparison with erbia, viz., lime and magnesia. As it seemed desirable to prepare these oxides in precisely the same manner as the erbia, some calcium and magnesium nitrates were made chemically pure to ordinary tests, and then used in the preparation of the respective oxides.

"The oxyhydrogen flame was employed as the chief source of heat. The hydrogen was made from zinc and sulphuric acid in the usual way, and the oxygen from potassium chlorate. As both gases are certain to be contaminated with traces of acids, I took the precaution of passing each gas through a long tube filled with fragments of solid potassium hydrate. If this plan were not adopted, the traces of acid which would find their way into the hydrogen or oxyhydrogen flame might produce volatile compounds with the earths, and so lead to mistakes.

"1. *Experiments with Magnesia.*—A loop of stout platinum wire was moistened with syrupy phosphoric acid, and some magnesium nitrate made to adhere. The nitrate was then heated in the hydrogen flame, and a residue of magnesia obtained. No lines were observed in the spectrum of the light emitted by the incandescent earth, and when the latter was intensely heated in the oxyhydrogen jet only a continuous spectrum was seen."

"2. *Experiments with Lime.*—A platinum wire, of the same thickness as the last, was moistened with the phosphoric acid, some calcium nitrate was then taken up in the loop, and heated in the hydrogen flame until a residue of lime was obtained. At the outset, the calcium-spectrum was observed, but the light speedily gave only a continuous spectrum. The lime and loop of wire were kept well enveloped in the hydrogen flame for nearly half an hour, in order to ensure the complete decomposition of the nitrate. During this time, no lines could be detected on the background of the continuous spectrum, or in the spectrum of

* For the spectra of metallic strontium, barium, and calcium, see *Phil. Trans.* 1864, p. 145, and Plates 1 and 2. Both forms of the spectra of these substances are represented by Thalen in his "Spektralanalyse."

† Roscoe's "Spectrum Analysis," p. 175, and *Proc. Lit. and Phil. Soc. Manchester*, April 1, 1870. See also A. Mitscherlich, "Ueber der Spektren der Verbindungen," S. 10.

* "Since writing the above, I have succeeded in observing the bright lines described by Mr. Huggins as occurring in the spectrum of the flame surrounding the incandescent magnesia. In the earlier experiments I probably admitted too much oxygen to the mixed gas-flame in the first instance."

the flame surrounding the lime. More hydrogen was now turned on, and oxygen slowly admitted, the light being examined with the spectroscopic during the time. When the proportion of oxygen had reached a certain point, faint traces of the two brightest Ca lines appeared on the bright background, and the intensity of these lines increased with the amount of oxygen admitted up to a definite extent. When a certain proportion of oxygen was exceeded, the lines became less distinct. The best results were obtained when the hydrogen was decidedly in excess of the oxygen in the flame—that is to say, more than in the proportion of 2 : 1.

"When the slit of the spectroscopic was pointed in such a way that only the light from the flame surrounding the incandescent lime entered the instrument, all the Ca lines and bands were observed with great ease without a continuous spectrum. On looking at the mantle of flame with the naked eye, it was easy to perceive a reddish tinge. I next maintained the small fragment of lime at the highest temperature its supporting wire was capable of resisting for *three hours*; at the end of this time, the Ca lines were as strongly marked as before, and the lime on the wire had very appreciably diminished in amount. The same results were obtained when no phosphoric acid was employed to attach the calcium nitrate to the wire in the first instance.

"Again, a piece of well-burned quicklime, of very small size, was heated alone on a platinum wire for more than an hour, and the bright Ca lines were seen during the whole time.

"From the results of these experiments, we must draw the conclusions—(1) that, when lime is sufficiently heated, the light which it emits is derived in part from the incandescent solid, and partly from ignited vapour; (2) that lime is either volatile *as such*, or that in the first instance it suffers reduction by the excess of hydrogen in the flame, the luminous vapour of calcium then giving its own peculiar spectrum.

"3. *Experiments with Erbium.*—The specimen of erbium nitrate which you kindly gave me was attached to a platinum loop with syrupy phosphoric acid, as usual, and decomposition of the salt effected in the plain hydrogen flame. After heating for a short time in this way, the chief green line of erbium became visible, but seen upon the continuous spectrum. Oxygen was now turned slowly into the flame. As the temperature rose, two of the other bright lines of the earth were seen. The best observations were made when the oxyhydrogen flame had hydrogen in excess, and the erbium was kept in such a position that it was very strongly ignited. The erbium lines were most distinctly seen when the slit of the spectroscopic took in the light from the extreme edge of the incandescent solid. When the bright lines were best observed, the continuous spectrum was relatively faint. Again, when the slit was made to cut the edge of the ignited bead of the earth, the strong green line of erbium was seen to extend to a very small, but appreciable, distance above or below (as the case might be) the continuous spectrum. I could only observe this for the strong line. I failed to get any trace of lines in the spectrum of the flame beyond the incandescent erbium.

"The erbium was next heated in the oxyhydrogen flame to the maximum temperature that the wire would bear for *three and a half hours*, but the green line was seen to be just as strongly marked at the end as at the beginning of the experiment. The bulk of the erbium was so much reduced by this treatment, that I have now scarcely a trace left.

"From the results of these experiments, I think we must conclude—(1) that the light emitted by incandescent erbium is derived chiefly from the ignited solid, but that the bright lines observed in its spectrum have, as their source, a luminous vapour of extremely low tension at even the highest temperature of the oxyhydrogen flame; (2) that this interrupted spectrum belongs either to erbium or to its oxide.

"If these conclusions are true, it follows that erbium is not an exception to the ordinary law.

"It would appear that, in these experiments, three substances have been employed, varying in their degree of volatility. At the temperature of the oxyhydrogen flame, magnesia appears to be less volatile than lime; but I am in doubt what relative volatility to assign to erbium, since its spectrum of bright lines can be seen when the earth is heated in the plain hydrogen flame, and yet at the much higher temperature of the oxyhydrogen jet the volume of luminous vapour does not appear to materially increase.

"Finally, we have yet to learn whether or not in all these cases reduction of the oxide precedes volatilisation; if reduction takes place, the luminous vapour must be that of the metal. The settlement of this question would no doubt be very difficult. But I rather incline to the view that the vapour whose spectrum is obtained on igniting these earths is that of the metal; for I find that the bright lines are most easily observed when hydrogen is present in excess in the oxyhydrogen flame. Moreover, the actual amount of matter volatilised on very prolonged heating is really very small, and this circumstance appears to favour the view that a slow surface-reduction is in progress."

OBITUARY.

WILLIAM ALLEN MILLER.

PROFESSOR MILLER, of King's College, London, died at Liverpool, of apoplexy, on Friday, the 30th of September. He left London on the 13th of September for the British Association, and was taken ill on the journey.

William Allen Miller was born at Ipswich, in Suffolk, on the 17th of December, 1817. He was carefully educated by his mother, who seems to have imparted to her son much of her own quiet, sagacious nature. He spent one year in Merchant Taylors' School, and two years in a school belonging to the Society of Friends, at Ackworth, in Yorkshire, where lectures on elementary chemistry were delivered, and from which young Miller imbibed a taste for that science. He was also much impressed with the phenomena of the stars as seen through a telescope which one of the masters used to exhibit to the pupils. These early impressions bore fruit in the chemistry of the stars, with which his name is now permanently associated. His training at Ackworth imparted to his manner that quiet simplicity which marks the members of the Society of Friends. At the age of fifteen he was apprenticed to his uncle, who was surgeon to the General Hospital at Birmingham. After five years he entered the Medical Department of King's College, where his knowledge of chemistry attracted the attention of Professor Daniell, who during the illness of the laboratory assistant engaged his services. This was the turning point in his career. In 1839 he gained the Warneford Prize for the encouragement of theological studies among medical students. In 1840 he visited Germany, and passed some time in Liebig's laboratory at Giessen. In the same year he was appointed to the post of Demonstrator in the Laboratory of King's College. In 1841 he became Assistant Lecturer to Professor Daniell, and also took his degree of M.D. in the University of London. He also assisted Professor Daniell in various scientific enquiries, and conducted the experiments on the electrolysis of saline compounds, his name being associated with that of Daniell in the paper that appeared in the *Phil. Trans.* for 1844. In the following year he became a Fellow of the Royal Society, and on the death of Professor Daniell succeeded to the vacant chair. During a quarter of a century, he continued to lecture with unceasing activity, and to take part in the management of the College, every one, from the Principal

and Professors to the youngest student, being anxious to obtain his advice and assistance. It was impossible to come into contact with him without feeling oneself in the presence of a man of pure nature, of spotless integrity, of sound and sagacious judgment, and of true gentlemanly feeling. His loss will be deeply felt, especially in King's College; in the Royal Society, of which he was Treasurer and Vice-President; in the Mint, and the Bank of England, where he was one of the Assayers. He will be missed in the Courts of Law, where his clear perception of patented processes and his strong sense of justice made him respected alike by Judge and Counsel. He will be missed by the manufacturers who sought his advice; but most of all he will be missed by the few friends who had his confidence. There is no man since Faraday whose loss will be so much mourned and regretted. He was buried at Norwood Cemetery on Wednesday last by the side of his wife, whom he survived one year. He died on the anniversary of her burial.

Prof. Miller bore his honours lightly; but perhaps it would be wrong to omit that he received the degree of LL.D. at the University of Edinburgh; that of D.C.L. at the University of Oxford, in June, 1868; and that of LL.D. at the University of Cambridge, in May, 1869, after giving the Reade Lecture. He also received the gold medal of the Astronomical Society, in conjunction with his friend and fellow worker, Mr. Huggins.

C. T.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopædic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

Note. All degrees of temperature are Centigrade, unless otherwise expressed.

[In consequence of the war on the Continent, several of the foreign journals have failed to reach us; we shall, however, give abstracts of them as soon as they are received.]

Annalen der Chemie und Pharmacie, August, 1870.

This number contains the following original papers and memoirs:—

The Iva (Achillea Moschata).—Dr. A. von Planta-Reichenau.—The subject of this memoir is a celebrated plant, a native of the Swiss mountains, and for centuries has been in high repute as a medicinal agent. The author first refers briefly to some historical facts bearing upon the Iva and its use; and then states that, as nothing is yet known in reference to the chemistry of this substance, he, having an excellent opportunity to procure the herb, undertook the exhaustive research of the same.—The lengthy memoir treats on essential oil of Iva, which, in the crude state, has a bluish green colour, a taste somewhat akin to oil of peppermint, while its smell is not disagreeable; its sp. gr., at 15°, is 0.9345; formula, $C_{26}H_{40}O$. The pure oil, boiling at between 170° and 210°, is a pale yellow-coloured fluid, exhibiting a peculiar strong ethereal smell; its taste is bitter, but, at the same time, like peppermint; the formula of the pure substance is $C_{24}H_{40}O_2$. Iva-in, an oleo-resinous bitter matter, readily soluble in water and alcohol, is the hydrate of the Iva oil. Stearic acid is also present in the herb, and, moreover, three other substances, which the author has called achilleine, moschatine and achilletine, the latter being the product of the decomposition of achilleine. This latter is a peculiar alkaloid, containing $C_{10}H_{15}N_3O_{14}$.

Analysis of the Water of the Thermal Spring of Ragaz-Plafers.—Dr. A. von Planta-Reichenau.—The spring alluded to is situated in the Canton St. Gall, Switzerland. The taste of this water is like that of warm distilled water; its temperature, at the source, 37.5°; sp. gr., 1.0005. 10,000 parts of this water contain—Sulphate of potassa, 0.0746; sulphate of soda, 0.3204; chloride of lithium, 0.0020; chloride of sodium, 0.4934; iodide of sodium, 0.0001; bromide of sodium, 0.0002; borate of soda, 0.0038; carbonate of soda, 0.0613 (all carbonates have been calculated as monocarbonates); carbonate of lime, 1.3064; carbonate of magnesia, 0.5306; carbonate of strontia, 0.0152; carbonate of baryta, 0.0064; carbonate of protoxide of iron, 0.0172; phosphate of alumina, 0.0091; silica, 0.1408; traces of rubidium, cesium, and thallium—Total of solid constituents, 2.9905. 10,000 c.c. of the water con-

tain 119.2 c.c. of gas, consisting, in 100 parts, of—Carbonic acid, 16.43; oxygen, 24.24; nitrogen, 59.33.

Non-Existence of Chlor-Cyanhydrogen.—A. Naumann and E. Vogt.—This paper treats, at length, on the question, whether the chlor-cyanhydrogen, 2CyCl.CyH , can and does exist; and the conclusion the authors have come to, after a lengthy series of experiments, is, that it does not exist as a definite chemical compound.

Uroxic Acid, and the Chemical Constitution of Uric Acid.—Dr. A. Strecker.

Behaviour of Chloride of Platinum towards Lime and Baryta-Water.—E. Johannsen.—This lengthy essay treats on a series of binary compounds which lime and baryta form with chloride of platinum. The paper, an excellent monograph on this subject, contains the results of a great number of analyses. The main result is that platinum has a greater affinity for chlorine than calcium and barium.

Formation of Chloro-Maleic Acid from Benzol.—Dr. L. Carius.—The author describes, first, a series of reactions of the hydrate of chloric acid upon benzol, resulting in the formation of various bodies, among which monochlor-maleic acid, $C_6H_5ClO_4$, a crystalline substance, readily soluble in water, alcohol, and ether; fusing at 171°; boiling at 180°. This acid is bibasic. The author describes, at great length, several of its salts, some of which crystallise very readily.

Two Metallic Derivatives of Glycerine.—Dr. P. Schottländer.—This lengthy monograph treats on the preparation and constitution of some compounds of glycerine, or, rather, the radical glyceryl, C_3H_5 , with manganese, sodium, potassium, and strontium.

American Journal of Pharmacy, September, 1870.

This number contains the following original papers and memoirs relating to chemistry and collateral sciences:—

Most Delicate Colour-Test for the Detection of Strychnia.—W. T. Wenzel.—After referring at some length to the great variety of the precise limit of the sensibility of the colour tests usually applied for the detection of strychnia, and also discussing the best form of using and manner of applying these tests, the author says—In testing for minute portions of the alkaloid, it is a desideratum to use a reagent the proportionate relations and superior sensitiveness of which will admit of the successful demonstration of traces of the poison. In experimenting towards that end, I have found that a solution of 1 grain of permanganate of potassa in 2000 grms. of sulphuric acid is, *par excellence*, the test for that purpose. The author gives, further, a lengthy account of a series of experiments, instituted with various reagents, for the purpose of testing the delicacy of each of these for the detection of strychnia, the result being that the limit of positive recognition by the bichromate of potassa and sulphuric acid test may be placed at 1-100,000th, that of the chromic acid test at 1-600,000th, and that of the permanganate at 1-900,000th. As regards the use of the permanganate, the author distinctly states that the honour of its discovery belongs to Dr. Wm. A. Guy, of London.

Phosphate of Lime in Acetic Acid.—W. H. Bruckner.—The author relates that, while engaged in analysing a sample of Charleston guano, he had occasion to use acetic acid, and, finding the results of his analysis unsatisfactory, and differing too much, he found, on testing the acetic acid (sold as chemically pure), to contain a not inconsiderable quantity of phosphate of lime; but the percentage of this impurity present was not determined, neither is any clue given to the way in which this material came to be present in the acid.

Production of Iodine and Bromine.—W. H. Chandler.—After referring at length to the various sources from which the two haloids alluded to are derived, the author mentions a few instances of the quantity of the elements above named present in some of the waters of saline springs in the United States, where iodine and bromine were first discovered in 1830—the former body in the Saratoga spring-waters, and the latter in the salines of Onondaga. The quantity of bromine in the Saratoga spring-waters, as determined by Professor Chandler, reaches 3.63 grms. per gallon; in a brine of the Saginaw valley, Dr. Chilton found 7.65 grms. of bromine; while at Tarentum, Pa., 6 grms. of bromine and 4 grms. of iodine were reported by M. Hieren. Bromine is, we learn further from this paper, manufactured in the United States in considerable quantity; that for the current year will amount to 125,000 lbs. Iodine is not at present manufactured in the States, the supply being obtained from Europe, where its manufacture is confined to Great Britain and France; the annual production of these countries amounts to 200,000 lbs. The average product of iodine is 10 lbs. to the ton of kelp; and, since it requires 20 tons of wet seaweed to produce 1 ton of kelp, this total represents 400,000 tons of seaweed. At the present price, the iodine produced is of more value than the alkaline salts. The chief consumption of bromine and iodine is for medicinal purposes, in the form of salts; a small proportion is consumed in photography. Bromine has been proposed as a discharge in calico-printing, and was, to a limited extent, used as a disinfectant during the late American war.

New Sulphur Deposit.—A. B. Taylor.—The deposit here alluded to is in the island of Saba, a country of volcanic origin its highest point being about 2800 feet above sea level. In this island, a Netherlands possession, sulphur was recently quite accidentally discovered by an enterprising New Yorker, who visited the island in search of health. With the aid of some of the natives, he succeeded in quarrying about two sloop-loads of the crude mineral, which, on being brought to New York, was found to yield, on average, rather over 60 per cent of sulphur, while the Sicily mineral only yields about 30 per cent. The deposit is, considering the small size of the island, very extensive, and is of great value for the manufacturing interests of the United States; and, since the island is distant only about 1500 miles from New

York, it need not be wondered at that leases have been secured of the best tracts of sulphur deposit there by American firms.

Roasting of Coffee.—W. Procter.—When a cold prepared extract of roasted coffee is distilled with lime or magnesia, an alkaline distillate is obtained, which, by evaporation, after the addition of hydrochloric acid, and extracting with alcohol, yields a pure chloride of methyl-ammonium. This product is formed by the decomposition of caffeine when combined with tannic acid, as is the case in all coffees; pure caffeine yielding different products of decomposition, among which is cyanogen. In roasting coffee, a portion of the caffeine is volatilised together with some methylamine, while the larger amount remains with the coffee itself; half of the caffeine of the coffee is decomposed in this way. One sample which, before roasting, was found to contain 1.45 per cent, yielded afterwards only 0.65 per cent. The temperature at which these changes are effected is, in the case of Porto Rico, or green coffee, 275°, and in that of Java, yellow coffee, 250° to 255°. Caffeine is soluble in bisulphide of carbon and benzol, and in the latter menstruum to such an extent, that it may be used with advantage to prepare the pure alkaloid from raw coffee.

Snake Poison and its Antidote.—S. B. Higgins.—To this paper, although not an original one, having been published in the *Chemist and Druggist* (London, June 15, 1870), we call the attention of those of our readers who happen to reside in countries where venomous snakes abound. The main gist of the contents of the memoir is, that the poisons of the poisonous snakes, and all animal poisons, have their specific antidote in the gall of the animal or reptile in which these poisons exist. The pure gall is mixed with very pure and very strong alcohol (95 per cent); 200 drops of that liquid, mixed with 20 drops of the gall, are thoroughly mixed; and of that mixture 5 drops are given at a time in half a tumblerful of water.

Neues Jahrbuch für Pharmacie, von Dr. F. Vorwerk (double number) May and June, 1870.

This number contains the following original papers and memoirs:—

Preparation and Constitution of Hyoscyamine in relation to the other Constituents of Semina Hyoscyami.—H. Hohn.—This lengthy monograph treats, in the first place, on the preparation of hyoscyamine from henbane seeds, carefully collected and fresh; secondly, the properties and composition of hyoscyamine are considered. The author found that hyoscyamine possesses, in a very high degree, the property of dilating the pupil of the eye; the alkaloid is precipitated by chloride of platinum only from concentrated solutions, and an excess of the platinum-salt re-dissolves the precipitate. The formula of the hyoscyamine is $C_{20}H_{23}N_2O_3 + HO$; and the author states that this body may be viewed as atropine, 1 atom of H of which has been replaced by 1 atom of methyl-ammonium, C_2H_5, H_2N ; and the formula of hyoscyamine may therefore be written—

The memoir further contains the following chapters:—Researches on a waxlike material obtained by the first purification of hyoscyamine in chloroform. The body herein alluded to has been called by the author, hyoscerine, a body fusing at about 210°, devoid of taste and smell, not sublimable, insoluble in water, readily soluble in strong boiling alcohol, and best so in ether and chloroform; the formula of this substance is $C_{22}H_{30}O_4$. Hyoscyamus seeds, moreover, contain a peculiar glycoside, Hyoscyipikrine, a peculiar volatile base, and a yellow-coloured nitrogen-containing resin; formula, $C_{11}H_{14}N_2O_{10}$.

Establishment and Capital required for the Manufacture of Artificial Mineral Waters, and on the Profits of that Trade.—Dr. E. Gressler.—This paper is a valuable contribution to our knowledge on this subject in a technical point of view; but, as regards the financial part of that business, it is only applicable to a portion of Germany.

Chemical Researches on the Fruit of the Laurel-Herb (*Daphne genkwa*), and more especially on a Fatty Oil contained therein.—Dr. A. Casseilmann.—This monograph is divided into the following divisions:—Investigation of the fatty oil.—This is a so-called drying oil, present in the fruit of the above-named plant to a percentage varying from 24 to 31.3; sp. gr. of the oil at 15°, 0.8903; not solidified at -10°, and not altered by a temperature of 160°. When freshly pressed, this oil has a smell resembling that of cantharides; its taste is very acid, but, by exposure to air for a few days, these characteristics are lost, owing to a change the oil undergoes by oxidation. The oil is readily soluble in ether, sulphide of carbon, and benzol, but very difficultly so in strong alcohol. This chapter treats, further, at great length, on the composition and constitution of this oil, the elementary constitution of which is expressed, in 100 parts, by—C, 76.69; H, 11.05; O, 12.26. The next division of this memoir treats on the investigation of the residue of the fruit after having been deprived of its fixed oil; and on the preparation of cocognine, a crystalline white-coloured body, readily soluble in alcohol, but not so in water; also soluble in ether. The composition of the fruit of the laurel-herb (a poisonous plant) is, in 100 parts—Etheral, or essential oil, a trace; fixed drying oil, 31.0; resin and wax soluble in ether, 3.58; an acid resin soluble in alcohol, 0.32; cocognine, 0.38; proteic compounds, 19.5; gum, mucilage, malic acid, bitter and colouring matters, and cellulose, 32.37; an organic matter (salts), 5.46; water, 7.39; total, 100.00.

Eau de Beauté de M. Bargasse.—Eau de beauté consists of—Bichloride of mercury, 80 centigrms.; camphor, 1 grm.; sulphate of zinc and solution of lead (*liquor plumbi acetici*), of each 4 grms.; rose-water, 250 grms.; and the yolk of one egg. This mixture is regularly in use (so the editor of this periodical states) by Creole ladies for beautifying their skin. A bottle containing this mixture in the above quantity is sold for about five shillings.

Polytechnisches Journal von Dingler, first number for June, 1870.

This number contains the following original papers relating to chemistry and collateral sciences:—

Description of an improved Pair of Compasses for Drawing Very Minute Circles.—M. Hellmann.—This description is accompanied by woodcuts.

Description of an Improved Zundnadelgeweter.—Dr. Dingler.

Analysis of Normal Fire-Clays adapted to the Manufacture of Various Objects.—Dr. C. Bischof.—This paper, which is, unfortunately too lengthy for any useful abstraction, contains, in the first place, a complete account of the methods of analysis of fire-clays, and the modes of testing these substances for their fire-resisting qualities. The author next details, at great length, a series of analyses of fire-clays, classified according to their value, beginning with a clay the resistance of which to fusion or softening is taken as =100, and ending with a clay which is only 10.

Glue which Stands Moisture without Softening.—Dr. Böttger.—Dissolve, in about 8 fluid ounces of strong methylated spirit, $\frac{1}{2}$ an ounce of sandarac and mastic; next, add $\frac{1}{2}$ an ounce of turpentine. This solution is then added to a hot, thick solution of glue to which isinglass has been added, and is next filtered, while hot, through cloth or a good sieve.

German Beer Bouquet.—Dr. Böttger.—This liquor consists of a solution of essential oil of lemons in light petroleum oil, and a coarse fuel oil containing spirit coloured by turmeric.

Second number for August, 1870.

This number contains the following original papers and memoirs relating to chemistry and allied sciences:—

Vertical Oil-Gas Retorts.—Dr. B. Hübner.—Illustrated with engravings.

Apparatus for Heating the Air of Hot-Blast Furnaces.—M. Whitwell.—Illustrated with a series of engravings.

On Cast-Iron, Wrought-Iron, and Steel, in reference to the Construction of Engines and Machinery.—Dr. Reiche.—This lengthy memoir treats on the physical, as well as chemical, properties of the materials alluded to, and on the defects they exhibit, due to the process of manufacture.

Behaviour of Sulphuret of Zinc while Exposed to Air.—A. Wagner.—The author records a series of experiments made with sulphuret of zinc, purposely prepared and left standing exposed to the air. The chief result of these experiments is, that sulphide of zinc hardly oxidises at all; and, for what little it does, it evolves sulphuretted hydrogen, and differs essentially from the sulphurets of iron and manganese, which become, under the same conditions, converted into oxides, sulphur being set free.

Preparation of Hydro-Fluosilicic Acid on the Small Scale.—F. Stolba.—The author describes, and illustrates with woodcuts, at great length and very minutely, the best method for the preparation of this reagent. The paper is too lengthy for useful abstraction.

Application of Rock-Salt to the Manufacture of Glass; and on the Direct Preparation of Soda Silicates from that Salt and Silicic Acid, both from Native and Artificial Silicates.—A. Unger.—Illustrated with a series of engravings.

Nitrogenous Substances Present in Beer: a Contribution to Brewing.—Dr. G. Feichter.—The author gives an exhaustive account of a series of experiments made with the view, not only to determine, quantitatively, the amount and nature of the nitrogenous matter present in beer, but also to show whence these nitrogenous compounds are derived, and the influence the various operations of the brewing process have upon the nature, as well as the quantity, of these substances. The chief result of these researches is that, a minimum excepted, the whole of the nitrogenous substances present in beer are derived from the albuminous matters present in the malt; and therefore the quantity of nitrogen found in the dry extract of beer may be calculated as albuminous matter.

Manufacture of Beer from Rice.—A. Belohnbeck.

Explanation of Steam-Boiler Explosions.—R. Wabner.—The author calls attention to the fact that hitherto no account has been taken of the possibility, which he proves to exist, that these explosions are occasioned sometimes by the formation of an explosive mixture of atmospheric air and the gases generated by the combustion of the fuel collected in the flues and tubes steam-boilers are provided with. The author gives instances of explosions which could be distinctly referred to this cause.

Preservation of Thallium.—Dr. Böttger.—The author states that, after having tried several methods, he has found that this readily-oxidisable metal is best kept unaltered by being kept in pure distilled water which has been boiled for a long time, to expel air, and cooled in a closed flask. An ingot of thallium fused under a layer of cyanide of potassium, and immersed in the liquid just mentioned, has preserved its silvery metallic surface unaltered for three years.

Moniteur Scientifique, No. 330, September 15, 1870.

The only original papers in this number relate to *brevets d'invention*, among which we notice the following:—

Improvements in the Manufacture of Stearine (Stearic Acid).—MM. Weiss and Co.—The process relates to a method of cooling of the oleic acid, obtained by the pressure of the stearine cakes, to a temperature of -5°. The acid, which always contains a certain proportion of stearine in solution, becomes, thus, a semi-fluid mass, which is

THE CHEMICAL NEWS.

VOL. XXII. No. 568.

ON THE ELECTRO-DEPOSITION OF COPPER AND BRASS.*

By W. H. WALENN, F.C.S.

THE present condition of the electro-deposition of copper and brass is put forward, in this paper, with sufficient reference to the history of the subject to enable comparatively recent improvements to be well understood, but treating the process in a practical manner and with reference to some improvements and manipulations that are adopted by the author.

The history of electro-metallurgy, as set forth by Smee, in 1851, comprises only that part of the subject which relates to the electro-deposition of metals from their neutral or acid solutions. With some isolated exceptions, no alkaline solution is there treated of. He therefore arrives at the conclusions—(1) That if hydrogen gas is evolved from the cathode during deposition, non-reguline metal is deposited; (2) that up to 1851, alloys were not able to be deposited by means of electricity, but that possibly they might be deposited without the evolution of hydrogen gas, by employing an "intense voltaic current."

To contrast with these views, it appears that, in 1851, there were from three to five practical methods of electro-depositing brass; and the present state of electro-deposition (independent of the improvements worked out by the author) shows that hydrogen gas is usually evolved from the cathode in copious bubbles during the deposition of reguline, but somewhat porous alloy from cyanide solutions, an intense voltaic arrangement being employed, in some respect to compensate for the waste of power induced by the evolved gas. The electrolysis of the solution of cyanide of copper in potassic cyanide also forms an exception to Smee's law for obtaining reguline metal, for during successful reguline deposition, hydrogen gas is evolved freely from this solution.

In alkaline solutions, the proneness to evolve hydrogen during deposition arises from the comparatively small quantity of metal in solution, and from the disposition of the metal of the alkali to go to the negative pole. The first cause can be removed by using a solution containing a greater percentage of metal than that usually employed; the second cause can be eradicated by providing, in excess, a decomposable compound radical that will take a certain amount of combined oxygen with it to the cathode.

Ordinarily, a solution containing the cyanides of copper and zinc, respectively, dissolved in a "solvent solution" consisting of a mixture of potassic cyanide with a salt of ammonium, is employed to deposit brass. This solution, however, evolves hydrogen copiously, and is only workable by means of two Grove's cells. The author finds that the evolution of gas may be either totally stopped, or much lessened, by dissolving as much of the metallic cyanides as the solution will take up, and then further charging the solution with the copper and zinc oxides. The evolution of gas may be totally stopped by the further addition of cupric ammonide, which may possibly carry the combined oxygen to the cathode according to the following equation:—

At the cathode before chemical reaction.

At the cathode after chemical reaction.

* Abstract of a paper read before the British Association, Liverpool Meeting, Section B.

Malaguti and Sarzeau's formula for cupric ammonide being used. That is to say, before decomposition or chemical reaction takes place, the whole of the cupric ammonide, together with the eliminated hydrogen, goes to the cathode; after the decomposition or chemical reaction has taken place, metallic copper is deposited, ammonia is in solution, and water is formed.

In treating the ordinary cyanide copper solution for the prevention of the evolution of hydrogen, the zinc cyanides or oxides, mentioned in the instance of the brass solution, are left out.

When the evolution of hydrogen has been stopped, a single Smee's cell is sufficient to deposit the alloy; but, in practice, a single Grove's cell, or equivalent magneto-electric power, is employed, in order to shorten the time of immersion in the electro-coating bath.

The author prefers to use potassic cyanide and neutral ammonium tartrate, when mixed with water, to form the solvent solution for either brass or copper. The quality of brass (yellow or red) depends upon the heat of the solution.

Acid solutions, in general, give a spreading, or matted deposit; alkaline solutions, a bristling one. The contact of the coating is promoted by working the solution hot. The article should be pickled, scrubbed with sand, washed, scrubbed with a portion of the depositing solution, and then placed in the depositing trough; after deposition, the article is washed, and dried in hot mahogany sawdust. Complete protection from rust, and a satisfactory coating for any purpose, is given by the use of the acid-depositing bath subsequent to that of the alkaline bath.

The subject-matter of this paper is illustrated by a calico-printing roll, weighing 125 lbs., with 29 lbs. of deposit upon it; and by twenty other results of the inventor's improvements.

The coating by means of the author's method of working is superior to that of any other known process. The invention is set forth, in detail, in Specifications Nos. 1540 (A.D. 1857) and 3930 (A.D. 1868); and it is applicable to the prevention of rust, the coating of plungers and other portions of machinery, and the lining of cylinders, &c. It is also applicable to architectural and other castings, and to many purposes which require the strength of iron and the beauty of brass.

ON THE PHENOMENA OF THE CRYSTALLISATION OF A DOUBLE SALT.*

By J. BERGER SPENCE, F.C.S.

As an illustration of a double salt, we cannot have a more forcible example than the tribe of alums.

As a rule, it is generally supposed, with one exception, they are easily made and crystallised.

Seeing the supposed difficulty which seems to surround this one exception, I was led to make many experiments to ascertain where the real difficulty lay, and in the following pages are a few of the records of my experiments.

In the manufacture of alum it would be a great desideratum if the manufacturer could dispense with the expensive items of ammonia and potash, and substitute soda in the production of this double salt, because the ammonia and potash are of no value to the paper-maker or the dyer. If these constituents could be given to the agriculturists it would be a benefit to both parties.

My attention has for some time been directed to this question, and I have made a considerable number of experiments to ascertain whether soda-alum could be produced as easily and as economically as its sister salts. I believe little or nothing was known of this compound before the beginning of this century. The first mention I have seen of it is in Ure's "Dictionary," where it says, "Mr. Winter first mentioned that another variety of alum

* Read before the British Association, Liverpool Meeting, Section B.

can be made with soda instead of potash, and that it is very difficult to crystallise." In Knapp's "Technology," the analysis of a natural soda-alum from South America is given. Watts's "Dictionary" says that it is found native in the island of Milo, in the Grecian Archipelago. Very few chemical works mention it fully, and most of the writers seem impressed with the idea that it is very difficult to crystallise. On this subject I have been experimenting for some months, and I find that the crystals can easily be produced if boiled down to the proper strength. The following are a few of my experiments:—

I prepared solutions of sulphate of alumina and sulphate of soda in their combining proportions to form alum. I boiled these solutions to 18°, 28°, 39°, and 47°, by Twaddle's hydrometer, and allowed them to stand for twenty-four hours; at the end of that time no crystals had made their appearance. In the case of ammonia-alum, a plentiful crop would have been obtained at 39° and 47°. It was not my object to make soda-alum from its equivalent salts, as that would be rather an unprofitable undertaking. These experiments were simply performed to find out the degree of crystallisation.

7000 grains of sulphate of alumina and 3360 sulphate of soda were dissolved and mixed; the solution was boiled down to 50°. It was standing for two days, and the yield of crystals was 150 grains. The cold solution was 65°; the mother-liquor was boiled to 67°. On cooling the solution, a white amorphous mass was formed (of this white mass I shall have to speak further on), which was re-dissolved and boiled down to 60°, and the yield of crystals was 4400 grains. The mother-liquor from the second crop was again boiled down to 60°, and the yield of crystals was 2390 grains. The total amount from the three crystallisations was 6940 grains.

The same quantities of salt were taken and boiled to 45°; 500 grains of strong sulphuric acid were added, which raised the strength to 52°; it stood for two days, and the yield of crystals was 260 grains. The mother-liquor was boiled down to 58°; the yield of crystals was 3700 grains, but these crystals did not look like pure alum, as they were more like sulphate of soda with crystals of alum interspersed. The solution was again boiled down to 60°; the crystals weighed 2200 grains. The total yield was 6160 grains.

A third experiment was made with the same quantity of salts, and the strength boiling was 55°. The yield was 2420 grains. The mother-liquor was boiled to 62°; the crystals weighed 3200 grains. The third crystallisation gave 1800 grains. The yield from the three was 7420.

Having now determined the crystallising-point, I proceeded to act upon shale which contained about 26 per cent of alumina. 1000 grains of calcined shale was treated with 400 grains of strong sulphuric acid boiled with water. 1000 grains of sulphate of soda was added, and the solution boiled down to 60°. The yield of crystals was 600 grains.

A second lot of shale, with three crystallisations, 1670. The same quantity of shale, with sulphate of ammonia and one crystallisation, 3090 grains.

2000 grains of shale, and the equivalent quantity of acid and soda, were added; the solutions boiled to 74°. No crystals were formed, but instead, an amorphous mass. This was re-dissolved, and the strength was 71°; still this amorphous mass was formed. After three days, this magma was gradually transformed into crystals, and the yield was 1680 grains. The mother-liquor was boiled to 62°, stood for two days, and the crystals weighed 1210 grains. The mother-liquor in the third crystallisation yielded 450 grains. The total amount of crystals was 3340 grains.

The same experiment with shale and sulphate of ammonia and one crystallisation, 6180 grains.

My last and conclusive experiments were made upon soda and ammonia-alums, so that, by comparison, I should be enabled to judge whether sulphate of soda or sulphate of ammonia would be the most economical for forming alum. The atomic weight of the two salts was taken, and boiled to different degrees of specific gravity.

Twaddle's hydrometer was used, and the solutions were all allowed about the same time for crystallisation.

100 parts of a mixture of sulphate of alumina and sulphate of soda, in their atomic proportions, will form 113·3 parts of soda-alum—

100 parts of the mixed salts were boiled down to 30° to see how much alum would be formed, likewise to 40°, 50°, and so on.

Soda-Alum, $Al_2O_3SO_3 + NaOSO_3 + 24H_2O$.

When the alums are formed and are re-dissolved and re-crystallised the loss is very considerable in the case of soda-alum, as the following table will show.

A definite quantity of alum was dissolved in water, and boiled down as before to various specific gravities.

When soda-alum was boiled to 20° no crystals were formed, but in the case of ammonia-alum 80·15 per cent crystallised out.

Percentage of Alum which Crystallised Out at Varying Specific Gravities.—In most cases 4000 grains of the salts were taken: the solutions stood about twenty hours, but in the case of the soda-alums the solution stood a much longer time, as at 40°, 50°, and 60° not a crystal was formed at the end of twelve hours; the solutions were well stirred and then set aside for twenty-four hours.

" "	60	 99·40
" "	63	 99·50
" "	68	 99·70

By these tables we see the very great disparity which exists, as regards the solubility of the two salts. At 68° soda-alum is more than 25 per cent behind ammonia-alum

at the same strength, and again it requires from three to four days for the crystals of soda-alum to form, whereas a few hours was sufficient for the ammonia salt.

In the first portion of this paper I have mentioned several times about a white amorphous mass which I always found on boiling the solutions of soda-alum to a high specific gravity. In my first experiments this annoyed me considerably, as I saw no way of overcoming the difficulty. Once when I boiled a solution of soda-alum to 68°, the customary white mass appeared on cooling. I put it on one side for a day or so, and on again examining it, I saw the surface was crystalline. I allowed it to stand for a few days longer, and day by day I watched it. The solution was put aside in a beaker so that I was enabled to watch the growth of the crystals. I was surprised to find at the end of the week that the whole of the white mass had disappeared, and in its place were large crystals of alum. It was most interesting to study the growth of the crystals as they grew from the top downwards, and according to the quantity of the amorphous mass so is the time for the crystals to form. I have examined this mass under the microscope with a quarter inch glass to see if I could detect any form; there was not the slightest crystalline appearance. The only explanation of this singular phenomenon which I can give is, that the alum is not really formed until the crystals appear, and time is requisite for them to unite and form the double salt; or again, may it not be that the high temperature to which the alum is exposed at the high specific gravity drives off the water of crystallisation, or some of it, thus giving an alum with minus its equivalent of water.

The important point was then to see the exact degree where the crystals merged into the amorphous condition and *vice versa*. For that experiment I used the mother liquors from the various crops of crystals.

The first portion was boiled to 64°: after twelve hours there was a crop of good crystals with a little of the amorphous mass mixed with the crystals.

At 65° a white mass with a honeycombed structure with crystals in the small holes.

At 66°, after twelve hours, half was a white mass, and the other half was crystals.

At 67°, after twelve hours, a white mass with very little signs of crystallisation about it.

At 63° the same as 67°.

The next point to determine was to ascertain how long it was before the white mass became converted into crystals. Here I found a variation extending from days to weeks, according to the strength of the solutions. The solution, which was boiled down to 63°, required three days for the crystals to form. One at 68°, a week. At 74° and 76° required three weeks, and another at 84° did not show any sign of crystallisation even at the end of three weeks, but was a white cake without mother liquor. On breaking the cake up, here and there crystals of alum were to be seen, bearing a faint resemblance to Fontainebleau sandstone.

From these experiments to obtain crystals we learn that the solutions should be at 60° at the boiling temperature, but they must not exceed 62°. Where time is of not much object the solutions may be boiled down to 68°, or even 70°.

On dissolving the crystals of soda-alum in water which is moderately hot, the white powder makes its appearance, and disappears in boiling. In this case, may it not be the sulphate of soda is dissolved first, leaving the sulphate of alumina to be dissolved afterwards. It will be seen that it is almost impracticable to make soda-alum on the large scale in competition with its sister compounds, when, in the first place, it is found that the solutions vary considerably in their crystallising power, for I have found sometimes that I could procure the crystals in two days, when at other times they have taken a week to form. Yet if the boiling solution is kept at 62°, a good crop may be reaped, though it would be much smaller than ammonia-

alum under the same circumstances. In the second place, the white amorphous mass which is formed in strong solutions would present considerable difficulties on the large scale, though, if time be given, ultimately the whole mass will be converted into crystals. Here, again, the time varies in the transformation of the amorphous to the crystalline condition. From the four experiments which I made on the mother liquors, boiling them to various specific gravities, the amorphous masses were several days in the transition state. In the case of another solution boiled to 68° it required six days for their complete conversion, and the higher the degree the longer is the time required for the change. I found if the masses were allowed to remain undisturbed the change was quicker than when they were disturbed with a rod.

In the third place, the excessive solubility of the salt is, I think, an insuperable difficulty; for if we turn back to the table of comparison, we find that when the soda-alum is re-crystallised and boiled down to 63° it takes three days for the crystals to form, and the percentage obtained is only 59.57, whereas, in the case of ammonia-alum, twenty-four hours are all that is required, and the percentage is 99.5.

The crystals of soda-alum differ a little in their form from the ordinary alums. The finest crystals are obtained from the amorphous mass, and these are octahedrons covered with minute triangles, as if the crystals were built up from the sides of pyramids.

There is certainly one advantage which the soda-alum possesses; that is, the cost of the sulphate of soda is trifling compared with sulphate of ammonia; and as the consumption of this latter material is gradually increasing, owing to its high value as a fertiliser, and as the agriculturist is now beginning to see the great value of these nitrogenous products, and as their value is lost in alum, it may ultimately, now that the practicability of producing soda-alum on the commercial scale has been demonstrated, even with all the difficulty of crystallisation, be a more economical way of producing this double salt.

ON THE RETENTION OF ORGANIC NITROGEN BY CHARCOAL.*

By EDWARD C. C. STANFORD, F.C.S.

TWELVE months' additional experience of the method of removing house excreta, which I introduced in a paper read before this Section last year, has fully confirmed all the advantages I then claimed for it. The use of X charcoal—that is, charcoal derived from the excreta itself—fully meets the only difficulties urged against the use of a dry system in large towns. The great power of the deodoriser employed reduces to a minimum the quantity required; and the source of supply is constant. Practically, once a year is quite often enough to empty the vault of an ordinary house; the amount to be removed is less than the house ashes, and the removal is even less offensive.

It has been applied to a large work and a number of private houses, and all who have inspected these acknowledge the arrangements to be a perfect solution of the difficulty. The process secures the whole value of the excreta, either to apply direct to the land, or in the form of sulphate of ammonia, and an animal charcoal second in value only to that derived from bones.

The only serious chemical objection that has been raised against the use of charcoal is, that its action upon organic nitrogenous matter is generally assumed to be that of a powerful oxidiser. Its powerful action on the carcass of an animal buried in it has led to the conclusion that the nitrogenous matter is oxidised into nitrates. It is, at any rate, a common opinion amongst chemists that charcoal

* Read before the British Association, Liverpool Meeting, Section B

cannot be economically used in fish or flesh manures, because, in some way or other, the manure loses a good deal of its nitrogen. This opinion rests on insufficient evidence. The action of charcoal on organic nitrogenous matter has never, as far as I know, been the subject of definite investigation. Is there a loss of nitrogen, and if there is, what becomes of it? These are questions which at present cannot be decidedly answered.

Dr. Stenhouse, in a lecture delivered at the Royal Institution, in 1855, first brought the subject forward; he found appreciable quantities of nitric acid in wood charcoal which had covered the body of a dog for six months. But the actual results of mixing nitrogenous animal matters with different kinds of charcoal have never been thoroughly investigated. The subject is important; and I am induced to submit some incomplete researches, as a first instalment of what promises to be a wide field of inquiry. Its bearing on the profitable use of charcoal as a means of securing the whole value of town excreta is obvious. Any serious loss of nitrogen would invalidate the process.

I showed, last year, that, with either fluid or solid excreta, there was no loss, as far as my experiments had extended. I pointed out, also, that I expected no loss from oxidation, as both must already be regarded as oxidised compounds. My experiments since extend over a long period, and I have included meat as one of the nitrogenous matters used; in all, however, I find no loss of nitrogen, no oxidation, and no formation of nitrates. Three mixtures were made on March 1st, and left in loosely-covered dishes in the laboratory—

No. 1 consisted of $\frac{1}{2}$ lb. of meat cut in fine pieces, and $\frac{1}{2}$ lb. of seaweed charcoal from tangle.

No. 2.—10 lbs. of urine, and 1 lb. of seaweed charcoal, evaporated down to about 2 lbs.

No. 3.—2 lbs. of the ordinary produce of the dry closet used with charcoal, which contains about equal parts of mixed excreta and X charcoal.

The mixtures were not weighed again till May 7th, and then were weighed and tested monthly for nitrogen till September 7th. The following table shows the weights, in ounces, and percentage analyses:—

	MEAT.		URINE.		EXCRETA.	
	Weight.	Nitro- gen.	Weight.	Nitro- gen.	Weight.	Nitro- gen.
	ozs.	per cent.	ozs.	per cent.	ozs.	per cent.
May 7th ..	9.50	2.36	23.00	5.75	14.00	1.08
June 7th ..	9.25	2.14	22.75	5.52	13.75	1.06
July 7th ..	9.00	2.19	22.50	5.50	13.50	1.06
August 7th ..	8.75	2.22	22.25	5.62	13.25	1.10
September 7th	8.50	2.14	22.00	5.50	13.00	1.10

There was no loss of weight after May 7th, the differences in the table being the amounts taken for analysis. The nitrogen was estimated by combustion with soda-lime and precipitation with platinum; except in the case of the urine, where the proportion was large enough to estimate the ammonia by test-acid. Large samples were taken to ensure uniformity. The mixtures were all difficult to sample; and when this is considered, the variations in the analyses are within the limits of error. They conclusively show that for six months there was no loss of nitrogen; no trace of nitrates could be detected. I regret that I have no data between the time of mixing and May 7th, but I fully expected to see the nitrogen in the meat experiment gradually diminish, so as to compare it with the other two experiments, where I expected the nitrogen to remain constant. I have others in progress which will supply this omission. The nitrogens are, however, pretty near the theoretical quantities. At any rate, the experiments show that mixtures of various nitrogenous matter of animal origin remained mixed with seaweed charcoal and X charcoal in a perfect state of deodorisation, and freely exposed to the air without the formation of nitrates or loss of nitrogen; and this is all I wish to prove for the

present. I hope, in a subsequent paper, to show also the effect of wood and bone charcoal on meat, both dry and moistened with water, which will probably materially effect the result.

I choose these charcoals as the representatives of the opposite ends of the charcoal series: the former being nearly pure carbon, and the latter containing but little carbon comparatively. Seaweed charcoal and X charcoal have a composition about intermediate; as both, however, contain a good deal of carbonate of calcium, I would expect them to pre-dispose to the formation of nitrates.

Charcoal is the best medium for converting fish and flesh offal of all kinds into inoffensive manure, if the nitrogen can be retained; I expect to show that the fear of its loss is, to a great extent, unfounded.

NOTE ON CLAUDET'S PROCESS FOR THE EXTRACTION OF SILVER.*

By J. ARTHUR PHILLIPS.

It is well known to the chemical trade that a remarkable increase in the price of brimstone took place in the year 1838, when the King of Naples granted a monopoly of Sicilian sulphur to Messrs. Taix and Co., of Marseilles, and that the immediate result was the employment of iron pyrites, as a source of sulphur, in the manufacture of sulphuric acid.

The consumption of this mineral rapidly increased from that date, and for many years the supply was principally derived from the mines of Cornwall, and from those of Wicklow, in Ireland.

About the year 1853, pyrites, containing a small percentage of copper, began to be imported from Spain and Portugal, and considerable quantities of ordinary pyrites are now also derived from Norway.

The increased importance of this branch of industry will, however, be appreciated when it is stated that the annual consumption, in the United Kingdom, of pyrites for the manufacture of sulphuric acid is now about 350,000 tons, of which at least 250,000 tons contain a sufficient amount of copper to render its treatment for that metal commercially advantageous.

The principal mines from which the chemical trade is supplied with cupreous pyrites are those of Mr. James Mason, at San Domingos, in Portugal, and those of the Tharsis Sulphur and Copper Company, in Spain.

The ores from these localities do not differ very materially from each other, and the following analysis, of a specimen from Mr. Mason's mines, may be taken as representing an average sample:—

Analysis of Mason's Pyrites.

Sulphur	48.90
Arsenic	0.47
Iron	43.55
Copper	3.10
Zinc	0.35
Lead	0.93
Lime	0.20
Insoluble rock	0.73
Moisture	0.70
Oxygen and loss	1.07

100.00†

In the manufacture of sulphuric acid this pyrites is burnt in kilns supplied with a limited amount of air, the products of combustion being from thence conducted into

* Read before the British Association, Liverpool Meeting, Section B.

† In addition to the above, this pyrites yields traces of thallium, cobalt, nickel, manganese, silver, and gold, and occasionally bismuth and antimony. See Mr. Claudet's analysis, *Journal of Chemical Society*, May, 1868.

lead chambers, as in the case of vitriol manufactured from ordinary brimstone.

The resulting residue, or "burnt ore," was formerly to a large extent smelted for copper, and from the great amounts of oxide of iron present, acted as a valuable flux for the more siliceous ores of that metal.

Burnt ore resulting from the treatment of pyrites from the San Domingos Mines may be taken as having the following percentage composition:—

Analysis of Burnt Ore from the San Domingos Mines.

Sulphur	3.66
Arsenic	0.25
Iron	58.25 = 83.00 Fe ₂ O ₃
Copper	4.14
Zinc	0.37
Cobalt	traces
Lead	1.24
Lime	0.25
Insoluble matter	1.06
Moisture	3.85
Oxygen and loss	26.93

100.00

Silver 18 dwt. per ton.

Soluble in water=sulphate of copper 4.12 per cent = 1.65 Cu.

For several years past a large proportion of the burnt ore produced in the various chemical works of the country has been worked by what is known as "the wet process of extraction." The principal advantage of this method of treatment arises from the circumstance that the resulting "purple ore" or "blue billy" is a saleable product, and is largely employed, both in the blast-furnace and for "fettling" puddling furnaces.

By the process of liquid extraction at present usually employed, the burnt ore is first finely ground and sifted, and subsequently roasted with common salt until, by the oxidation of the metallic sulphides present, a portion of alkaline salt is converted into sulphate of soda, whilst the copper is, on the contrary, transformed into a soluble chloride.

The copper salt is subsequently removed by repeated washings, and the copper precipitated by iron in the metallic state, whilst the residual purple ore remains in the washing-vats.

It has been long known to those engaged in this business that the copper precipitate produced not only contains a notable quantity of silver but also distinct traces of gold. No attempt, however, to separate the precious metals, and to turn them to profitable account, had been made up to the commencement of the present year, when Mr. F. Claudet patented a process for the separation of silver from ordinary copper liquors by the addition of a soluble iodide.

The amount of silver present in burnt ore seldom exceeds 18 dwts. per ton; but as the whole of this is never obtained in solution, it follows that, dealing with such minute quantities, in order to obtain satisfactory commercial results, the process employed should be both cheap and expeditious.

The vats, in which the burnt ore which has been roasted with salt are lixiviated, generally receive some eight or nine successive washings, with either water or with water acidulated by hydrochloric acid, and of these the first three only contain a sufficient amount of silver to be worth working.

For the purpose of removing the soluble salts from the ground and washed ore, hot water is employed, and as a large proportion of the chloride of sodium used remains undecomposed, it acts as a solvent for the chloride of silver produced during the process of furnacing.

The analysis of the first washings from a copper tank gave the following results:—

Analysis of Strong Liquors. Contents per gallon of 70,000 grains. Sp. gr. by hydrometer 1.240.

	grs.
Sulphate of soda	10,092
Chloride of sodium	4,474
Chlorine (combined with metals)	4,630
Copper	3,700*
Zinc	480
Lead	40
Iron	32
Calcium	52
Silver	3.06

As, Sb, Bi, &c., not estimated.

Total Chlorine 7,347 = 12,106 NaCl.

„ Sulphuric acid .. 5,686 = 2,274 sulphur.

Proportion of copper to silver contained—

Copper	10,000
Silver	8.2

The respective amounts of copper, chlorine, sulphur, and silver contained per gallon in nine successive washings of one tank of ore are given in the following Table:—

Copper Liquors from nine washings of one Tank of Ore.

No. of washings.	Sp. gr.	No. of grains per gallon of 70,000 grains.			
		Copper.	Chlorine.	Sulphur.	Silver.
1st	1.285	5,230	10,798	1,324	4.06

Washings 1 and 2 contain 82.50 per cent of total silver.

„ 1, 2, and 3 contain 94.30 „ „ „

The several operations for the extraction of silver are conducted in the following manner; and as the first three washings contain nearly 95 per cent of the total amount of that metal dissolved, these alone are treated.

These liquors are first run into suitable wooden cisterns, each of a capacity of about 2700 gallons, where they are allowed to settle. The yield of silver per gallon is now ascertained by taking a measured quantity, to which are added hydrochloric acid, iodide of potassium, and a solution of acetate of lead. The precipitate thus obtained is thrown upon a filter, and, after being dried, is fused with a flux, consisting of a mixture of carbonate of soda, borax, and lampblack. The resulting argentiferous lead is passed to the cupel, and, from the weight of the button of silver obtained, the amount of that metal in a gallon of the liquor is estimated.

The liquor from the settling-vat is now allowed to flow into another of slightly larger capacity, whilst, at the same time, the exact amount of a soluble iodide, necessary to precipitate the silver present, is run into it from a graduated tank, together with a quantity of water equal to about one-tenth the volume of the copper liquor. During the filling of the second tank its contents are constantly stirred, and, when filled, a little lime-water is added, and it is allowed to settle during forty-eight hours.

The supernatant liquors are, after being assayed, run off, and the tank again filled, when the precipitate collected at the bottom is, about once a fortnight, washed into a vessel prepared for its reception.

This precipitate is chiefly composed of sulphate of lead, iodide of silver, and salts of copper, from which the latter are readily removed by washing with water acidulated by hydrochloric acid. Thus freed from salts of copper, the precipitate is decomposed by metallic zinc, which reduces the iodide of silver completely, and, to a certain extent,

* 405 grs. of this copper exist in the state of subchloride.

also the sulphate of lead. The result of this decomposition is—

1st. Iodide of zinc, which, after being standardised, is employed in subsequent operations to precipitate further quantities of silver.

2nd. A precipitate rich in silver, and also containing a valuable amount of gold.

The more important constituents contained in a sample of this substance were estimated with the following results:—

Moisture 25 per cent. Rough Analysis of Dried Sample.

	oz.	dwt.	gr.
Silver	4'455	per cent = 1455	6 0 per ton.
Gold	0'0595	= 19	8 12 „
Zinc	15'440		
Lead	56'400		
Copper	0'600		
Lime	1'100		
Iron	0'700		
Sulphuric acid	6'680		
Insoluble ..	7'600		

The results of nearly six months' experience of this process at the Widnes Metal Works show that $\frac{1}{2}$ ounce of silver and $\frac{1}{4}$ grain of gold may be extracted from each ton of ore worked at a total cost, including labour, loss of iodide, &c., of 8d. per ton, or 1s. 4d. per oz. of silver produced. If from this amount be deducted 6d., the value of the 3 grs. of gold contained in each ounce of silver, the cost of production, per oz. of silver, will be reduced to 10d., and the expense of working a ton of ore to 5d. This leaves a profit of about 2s. on each ton of ore worked.

The value of the precious metals extracted from each ton of ore treated is certainly not large, as the amount originally contained is very small. With richer ores, however, more satisfactory results would be obtained; but when it is stated that some of the copper extraction works operate on 30,000 tons of ore annually, it becomes evident that a profit of 2s. per ton is a most important consideration in a business in which vigorous competition has rendered the exercise of the strictest care and economy absolutely necessary.

ON THE ESTIMATION OF MANGANESE IN SPIEGELEISEN.

By J. SPEAR PARKER.

WHEN making determinations of manganese in spiegeleisens, I have frequently been struck by the fact that, when the solution is coloured blue by the presence of copper, that colouration invariably disappears after precipitation of the manganese as hydrated dioxide.

The method of analysis used is as follows:—The finely-divided spiegeleisen, after solution in hydrochloric acid, is peroxidised with potassium chlorate; the excess of chlorine boiled off, the solution diluted, brought to boiling, neutralised with ammonia, and the iron precipitated by addition of a boiling solution of ammonium acetate (feebly acid). After boiling for an hour, the precipitate is allowed to subside, then filtered and washed with boiling water. The residue is dissolved in hydrochloric acid, and the precipitation repeated. The two filtrates are concentrated to a small bulk by evaporation. When copper is present in appreciable amount, this solution has a distinct blue tint. If necessary, the solution is again filtered, carefully washed, the filtrate heated, slight excess of ammonia added, and bromine till the manganese is completely precipitated. After standing for twelve or eighteen hours, the precipitate is filtered; the filtrate is always colourless. The burning of the filter-paper, too, would generally communicate to the flame the peculiar green colour which is characteristic of compounds of copper.

A spiegeleisen usually contains 0·2 or 0·3 per cent of copper—sometimes 0·5, or even more; therefore the precipitation of the copper with the manganese would seriously impair the accuracy of the determination.

To place the matter beyond a doubt, the following experiments were tried:—The ignited proto-sesquioxide of manganese, obtained from 20 grains of a spiegeleisen containing copper, was dissolved in hydrochloric acid; the solution, which was of a bright green colour, was diluted and transferred to a weighed platinum crucible. A piece of pure zinc was added, and the crucible was almost immediately covered with a copper-red deposit. After complete precipitation of the copper, and solution of the zinc, the liquid was decanted, and the crucible washed several times with boiling water (allowing the particles to subside, and then decanting); finally, dried in the water-bath. The copper thus obtained weighed 0·07 gr.

A solution of manganous sulphate was then prepared, and two equal quantities measured by a pipette. The one after heating with ammonium acetate was precipitated by bromine; to the other, about a grain of crystallised cupric sulphate was added, and precipitation effected as before.

The proto-sesquioxide obtained from the first weighed 1·582 grs.; from the second, 1·823. The copper estimated in this gave 0·188 gr., equivalent to 0·235 gr. of cupric oxide. Subtracting this from the total weight of the second precipitate, leaves 1·588 grs.

By direct determination, manganese = 1·144 grs.

Precipitated with copper, which was subsequently determined and calculated to exist as CuO, manganese = 1·140 grs.

To ascertain how much copper it was possible to precipitate with the manganese, a solution containing cupric and manganous sulphates, in equal amount, was precipitated with bromine (keeping the solution as nearly as possible neutral).

The precipitate is of a lighter brown when containing copper than the pure hydrated dioxide. On igniting, it first changed to a fine black colour; after strong and protracted ignition, to brown black. After weighing, the copper was determined as before—

$$\text{Mn}_2\text{O}_4 (+ \text{CuO}) = 2\cdot98 \text{ grs.}$$

$$\text{Copper} = 0\cdot70 \text{ „}$$

This is equivalent to 0·88 gr. of CuO; subtracting from the first amount, leaves 2·10 grs. of Mn_2O_4 , which contains 1·51 grs. of metallic manganese. There is, therefore, nearly 1 equivalent of copper to 2 of manganese. The copper can be extracted from the moist precipitate by boiling with strong solution of ammonia, or by digestion with cold dilute sulphuric acid (in the latter case, a small portion of manganese also is dissolved). It is probably present as a manganite of copper, corresponding to Mr. Weldon's acid manganite of calcium. This compound seems to be somewhat unstable; for if, during precipitation, the solution be allowed to become more strongly acid, or if, on the other hand, excess of ammonia be maintained throughout, the proportion of copper is considerably diminished, especially in the latter case.

Two methods may be used to remedy this error: either to separate the copper previous to the precipitation of the manganese; or to determine the amount of copper in the ignited oxide, and then subtract an equivalent amount of cupric oxide from the total weight of the precipitate.

In using the first method, 20 grains of the finely-divided spiegeleisen were completely dissolved in hydrochloric acid, diluted, and a current of sulphuretted hydrogen passed through the liquid. After standing for twelve hours, the solution was filtered and washed with water containing sulphuretted hydrogen; the filtrate was boiled, 10 grs. of potassium chlorate added, the iron separated, and the manganese estimated in the usual manner.

The following experiments were tried to test the accuracy of this method:—

(1). The manganese was estimated after separation of copper as above; gave 2·380 grs. of Mn_2O_4 = 8·57 per cent of manganese.

(2). The manganese estimated as usual after separation of iron only, gave 2.457 grs. of $Mn_3O_4 = 8.85$ per cent of manganese.

The copper was estimated in this precipitate by precipitation on a platinum crucible by zinc; gave 0.074 gr. of Cu = 0.093 gr. of CuO. Subtracting from the original weight, leaves 2.364 grs. of $Mn_3O_4 = 8.52$ per cent of manganese.

Two experiments similarly conducted gave—

(1). $Mn_3O_4 = 2.375$ grs. = 8.55 per cent of manganese.
(2). $Mn_3O_4 (+ CuO) = 2.459$ grs. = 8.86 per cent of manganese. Cu = 0.077 gr., equivalent to 0.096 of CuO. Subtracting, leaves $Mn_3O_4 = 2.363$ grs. = 8.51 per cent of manganese.

These results may be thus tabulated:—

Manganese by	1st expt.	2nd expt.
Usual method	8.85	8.86
After subtracting CuO ..	8.52	8.51
Previous separation of Cu..	8.57	8.55

In each of the experiments marked (1), a trace of copper escaped separation and could be detected in the ignited proto-sesquioxide.

If the method used be that of determining the copper in the precipitate, the estimation must be made with the greatest care, on account of the small quantity of copper present; the solution must be decanted immediately the zinc is completely dissolved, and excess of acid must be carefully avoided, otherwise the film of copper will partially re-dissolve.

It is evident that, if the precipitation be effected by ammonium sulphide or sodium carbonate, separation or estimation of the copper is likewise necessary.

Dr. Wolcott Gibbs proposed to precipitate manganese as ammonio-phosphate, weighing as pyrophosphate. This method gives very accurate results in pure solutions of manganese, but, in spite of every precaution, a minute amount of copper is dragged down with the precipitate in the presence of that element; it is also liable to the objection that calcium, magnesium, &c., when present, would also be precipitated.

The accurate determination of manganese in spiegel-eisen is of importance commercially; as, being the most important constituent, the value of the material is frequently judged by the percentage of that element alone, while the error introduced by the presence of copper is aggravated by the fact that, not only is copper worthless, but absolutely injurious.

The combining proportions used were—Mn, 55; Cu, 63.4; O, 16.

ON ALUMINIUM WEIGHTS.

By Dr. T. L. PHIPSON, F.C.S.

For the last ten years—that is, since May, 1860—I have made use of a set of aluminium (division of the gramme) weights. On the average these weights have been used at least twice or three times a-day for a period of somewhat more than ten years. They were supplied by MM. Collot, Frères, of Paris. Latterly, I have tested them and found them as accurate as the day on which they were first used. They are almost as brilliant as when new. The larger weights 0.5, 0.2, and 0.1 gramme show slight traces of tarnish, but their weights are still quite accurate.

During this period of ten years these weights have never been touched except by a pair of soft brass nippers, and they have never been left exposed to the air for more than a few minutes at a time. However, they have, of course, been exposed for a minute or two at intervals to an atmosphere more or less impregnated with acid

or alkaline vapours, and if we add these odd minutes together, it will be found that these gramme divisions in aluminium have had to undergo a considerable amount of "atmospheric influence" during the period of which I speak.

I need scarcely say what a luxury it is to use such large weights as these in comparison to the platinum gramme divisions, and I am surprised that they are not more generally adopted in our laboratories. The set contains 14 weights, from $\frac{1}{4}$ a gramme to $\frac{1}{4}$ a milligramme. As to brass or copper divisions, I have always considered them inaccurate, for they tarnish very rapidly in an atmosphere which, for that of a laboratory, might be considered tolerably pure. Weights of mallechort (a kind of German silver) resist much better than copper or brass weights; I have a set since the year 1856, the gramme divisions of which extend only to the centigramme, and are perfectly bright and accurate at the present day, but they have only been used occasionally.

The Cedars, Putney, S.W.

EXAMPLES FOR PRACTICE IN QUANTITATIVE CHEMICAL ANALYSIS.*

By FRANK H. STORER,

Professor in Massachusetts Institute of Technology.

(Continued from p. 163).

EXPERIMENT V.—Determination of Lime in Marble.

REDUCE a quantity of pure white marble to fine powder and dry it upon a water bath. Weigh out 3 or 4 grms. of the powder, place it in a beaker of about 700 c.c. capacity, and pour upon it 40 or 50 c.c. of water. Cover the beaker with a glass plate and add dilute chlorhydric acid, little by little, to the water, until the whole of the marble has dissolved. About 100 c.c. of the acid may be required to effect the solution. As soon as the marble has dissolved, fill the beaker half-full of water and boil the mixture. Add a solution of oxalate of ammonium in slight excess, together with enough ammonia water to make the mixture alkaline. Leave the mixture at rest for twelve hours or more, then transfer the clear supernatant fluid to a six-inch filter, and wash the precipitate in the beaker, four or five times, by decantation. Finally, transfer the precipitate to the filter, and wash and dry in the usual way. Heat the precipitate in a porcelain crucible for fifteen minutes to a temperature just below redness, in order to convert the oxalate to carbonate of calcium. If the material analysed were absolutely pure, and the work entirely accurate, the final weight of carbonate of calcium obtained would of course be identical with the weight of marble taken.

Since it is difficult to convert oxalate of calcium to the condition of carbonate, by ignition, without decomposing a portion of the latter, it is well to moisten the ignited precipitate (after it has been cooled and weighed) with a solution of carbonate of ammonium, to dry the mixture, first upon a water bath, and then over the lamp at a gentle heat, and again weigh it. This last weight will give the true amount of carbonate of calcium.

In our experiment 3.101 grms. of marble were taken, and 3.0975 grms. of carbonate of calcium were found. 3.0975 grms. of CaO, CO_2 represent 1.734 grms. of CaO. Hence we found 55.93 per cent of lime, instead of the 56.00 per cent required by theory.

Numerous forms of apparatus for determining the proportion of carbonic acid in limestone will be found figured in works relating to quantitative analysis.

(To be continued).

NOTICES OF BOOKS.

The Natural History of Commerce, with a Copious List of Commercial Terms and their Synonyms in Several Languages. By JOHN YEATS, LL.D., Fellow of the Geological Society of London; of the Royal Geographical Society; Member of the Society of Arts, &c. Assisted by several scientific gentlemen. London and New York: Cassell, Petter, and Galpin. 1870.

THE work before us, the first of a series, is one which we hope will be gladly welcomed and largely perused by those who must almost daily feel the want of a book of this nature. Undoubtedly there is a want of such books in the United Kingdom, and its merchants and manufacturers have reason to be indebted to the author, who in this volume delineates the principal divisions of the earth from an industrial point of view, and describes the varied contents of the inorganic and organic world—that is to say, the raw materials of commerce, according to their material value and importance. The book therefore comprises the geography and natural history of raw materials—the contents of that vast storehouse, the world at large, which ought to be familiar to all civilised men, and especially so to the mercantile classes of this country. The first part of the work contains—The Geography of the Home Country, the adjacent Continent, our Colonial Dependencies and Foreign Trade Connections. This first portion is subdivided into twelve chapters, viz.:—Raw Material; Our National Home; Geology of Great Britain; The United Kingdom—Ireland; The United Kingdom—Great Britain; British Fisheries; European Analogues of United Kingdom; the British Empire; British Colonies and Possessions; Foreign Produce—Europe; Asia; the New World; Nature and Man as Agents of Change. Part the second contains—The Commercial Products of the Vegetable Kingdom, subdivided into food plants, industrial, and medicinal plants. Part three—The Commercial Products of the Animal Kingdom, subdivided as follows:—Introduction; products of the class *Mammalia*; products of the class *Aves*; products of the class *Reptilia*; products of the class *Amphibia*; products of the class *Pisces*; products of the sub-kingdom *Mollusca*; products of the sub-kingdom *Annulosa*; products of the sub-kingdom *Radiata*; products of the sub-kingdom *Protozoa*. Part four—Raw Mineral Produce; subdivided into metals and minerals proper. The appendix contains—Vocabulary of the Names of Natural Productions in the principal European and Oriental Languages. Valuable as are the contents of the work, that value is largely increased by the addition of this excellent and very complete vocabulary, and for that alone the work should find a permanent place in mercantile offices among dictionaries of commerce and directories. Lastly, we have, illustrated by an excellent coloured frontispiece—The Geographical Distribution of Food and Industrial Plants.

It is a stigma to our days that works of this kind are not valued as they should be, while books of fiction and sentimental rubbish (partly the effect and partly the cause of an excitable nervous system) are read and bought with avidity. We therefore congratulate the author as well as the publishers for having the courage to undertake the issuing of such a work as this, which, moreover, has the merit of being written with brevity as well as accuracy, and is issued at a price which renders its acquisition by the many easy.

We have perused this volume with great pleasure; it supplies a want which those who are acquainted with the German and French works on what is characteristically called in German, "Waaren-Kunde," will best understand. This volume will be followed by two others from the same author's hand. The first, entitled "The Industrial and Political History of Commerce," will dwell upon the development and decay of the several nations that have successively taken a lead in arts rather than in arms; in it the uses and abuses of *Capital* will be chiefly con-

sidered, and the question submitted, Whether, notwithstanding serious lapses, mankind does not, as a whole, progress, and whether we may not speak of past ages as of wheat-ears, and say of them, they "ripen and die, yet live?" The third volume will have for its title, "The Technical History of Commerce," and will consist of a series of sketches on the growth of the industrial *Arts*, not of processes, which would lead into technology. It will deal with *Labour* principally, and the object is to show the heritage of wealth, both intellectual and material, enjoyed by the workman of the present day; it will contrast his position with that of any of his predecessors, and point out his duties to his fellow man as well as his obligations to posterity.

LABORATORY NOTES.

ON A CHEAP FORM OF VOLTAIC DECOMPOSITION APPARATUS.

THE decomposition tube, devised, I believe, by Dr. Hofmann, and described at p. 50 of his "Modern Chemistry," is an extremely elegant and luxurious piece of apparatus for showing analysis of bodies by electricity; but it has two defects, viz., that it is expensive to begin with, and very easily broken, either during its carriage, or by the mischances of the laboratory assistant. Experience of the fragile character of these tubes led me to make a more substantial apparatus, which, while it has the advantage of the ordinary tube, can be fitted up in any laboratory for a few shillings. The following is a description of the arrangement:—

A is a common pomade bottle, into which is fitted an india-rubber stopper, B, perforated with five holes (two

large, two small, and one medium size). Though the two large holes of the stopper pass two glass tubes, C, of about $\frac{1}{4}$ -inch diameter and 7 or 8 inches length. Each of these tubes is closed at the top by an india-rubber stopper carrying a piece of $\frac{1}{4}$ -inch glass tube, to which is attached a jet and pinch-cock, H. The electrodes are made as follows:—A piece of thick platinum wire is beaten out at one end to form a flat plate, and is then threaded through a piece of glass tubing rather shorter than itself. When this is done, the glass is melted on to the platinum, and the tube, with its contained wire, is bent in the form of

the letter J. A second piece of wire and tube is treated similarly to form the second electrode. When these are made, they are passed through the two small holes of the stopper, B, and project above it, as represented at D D. The electrodes are turned so that they may pass up into the tubes, c c. To the remaining hole of the stopper is fitted a tube, E, connected by a piece of caoutchouc tubing with a funnel, F, supported on the ring of a retort stand. The apparatus is now complete, and when the stopper with its appendages is fitted into the pomade bottle, is all ready for charging. This is done by pouring the acidulated water or other electrolyte into the funnel, F, at the same time opening the pinch-cocks to allow the air to escape. When the bottle and tubes are full, the pinch-cocks are closed, and all is ready for attaching the battery to the electrodes at D D. I omitted to mention that the tubes, c c, may be conveniently steadied, should this be necessary, by tying them against a cork wedge, as represented at G.

C. J. WOODWARD, B.Sc.

Midland Institute, Birmingham,
October, 1870.

OBITUARY.

AUGUSTUS MATTHIESSEN,

Who died last week, on the 6th of October, was born January 2nd, 1831, in London. He studied in Heidelberg, under Bunsen and Kirchhoff, and worked both in the chemical and physical laboratories.

His first piece of chemical work was published in the *Journal of the Chemical Society*, in the year 1856, under the title "On the Preparation of the Metals of the Alkalies and Alkaline Earths by Electrolysis." This research, a continuation of Bunsen's work on the subject, was carried out in Heidelberg, under Bunsen's inspection, and was crowned with success. The metals of the alkali-earths were then, for the first time, isolated and shown to be possessed of rather unexpected properties—calcium, for instance, being found to be a yellow metal particularly ductile and malleable, and having about the same degree of hardness as gold. It was shown that, although calcium is electro-negative to potassium and sodium (water being the exciting fluid), yet neither potassium nor sodium is capable of reducing chloride of calcium at high temperatures, and, therefore, that which had been described by other chemists as calcium obtained by such a process could not be the metal in question.

An extraordinary degree of manipulative skill was displayed in this investigation: and yet Matthiessen laboured under the physical difficulty of unsteadiness of hand (specially of the right hand), and in consequence of it wrote a most desperate kind of handwriting, as his friends can testify. He was, later in life, induced to give up writing with the right hand altogether, and to take to writing with the left.

Two other notices on the same subjects, viz.:—"On the Preparation of Strontium and Magnesium," and "On Barium," also occur in the same volume of the journal. An interesting fact brought to light in the former of these notices is that calcium is electro-positive to strontium (water being the exciting fluid). The note on barium, was to the effect that that metal could not be obtained as a regulus by the process which furnished buttons of calcium or strontium.

In the following year (1857), Kirchhoff communicated to *Poggendorff's Annalen*, a paper in Matthiessen's name, entitled "On the Electric Conductivity of Potassium, Sodium, Lithium, Magnesium, Calcium, and Strontium," and embodying the experimental results obtained by Matthiessen in the physical laboratory in Heidelberg.

From this paper it appears that, whilst Becquerel had

found the ratio of conductivity between potassium and silver to be 1·7 : 100, Matthiessen found it 22·6 : 100, both being observed at the same temperature, viz., 0° C. The device now so well known, of pressing out small portions of metal into thin wire by means of a steel press is also described in this paper. Matthiessen even managed to press out such substances as tellurium, bismuth, and antimony into thin wires, admirably adapted for physical determinations of various kinds.

Poggendorff's Annalen for 1858 contains two memoirs of Matthiessen's, viz., "On the Electric Conductivity of Metals," and "On the Thermo-Electric Series." In the *Philosophical Magazine* for the same year, Matthiessen had a paper "On the Coercitive Power of Pure Iron." About this time he returned to London, where he remained almost uninterruptedly till the end of his life.

In 1862 he was appointed to the chemical lectureship at the medical school of St. Mary's Hospital, and about the same period became a Fellow of the Royal Society. In 1869, he removed from St. Mary's to St. Bartholomew's Hospital, and, in the same year, the Royal Society awarded to him a Royal Medal, in acknowledgment of his researches. The physico-chemical work on metals, which, as has been said, was published in the years 1857 and 1858, was continued for a number of years, and published in a series of papers in the *Transactions of the Royal Society*.

Matthiessen also turned his attention to one of the departments of organic chemistry, viz., the chemistry of the opium-bases, which he investigated with conspicuous success. By exposing narcotine to the action of hydriodic acid, he and Mr. Foster obtained iodide of methyl in large quantities, and, as will be learnt on referring to their paper, actually attained to a knowledge of the structure of narcotine, which now awaits confirmation by synthetical methods.

The more recent work on morphia and codeia is fresh in the recollection of chemists. Some of it was done single-handed, and some with the co-operation of Mr. Wright. To medicine it has yielded apomorphia, a new agent in therapeutics. What further was in store is now withheld.

There is a fatality attending English official chemistry. Within the month one chemist has been stricken with acute mania, and next the epidemic seized upon poor Matthiessen, whom, in the dearth of English workers, we could so ill afford to lose. Overshadowed by a dark cloud, he poisoned himself with prussic acid.

J. A. W.

CORRESPONDENCE.

THE LATE DR. MILLER.

To the Editor of the *Chemical News*.

SIR,—May I suggest to yourself, and (through your kind intervention) to the scientific world, the desirability of honouring the memory of William Allen Miller, whose loss you feelingly communicate to your readers, by some permanent memento.

He had a diversity of claims upon our respect which render the combined action of his admirers more likely to effectuate good out of evil than happens in the case of every deceased philosopher.

A copious writer, an original observer, an experienced metropolitan lecturer, a conspicuous office-bearer in leading scientific societies, a graduate of London, Edinburgh, Cambridge, and Oxford, few men within the latter half of the 19th century have been better known (at least by name) to British students of nature, and fewer still equally valued for their personal amiabilities.

I would propose, therefore, with your favouring co-operation, and that of other leading English experimentalists, that we should raise, by subscription, a fund (to be vested in the Royal or Chemical Society, or in King's

College), the interest of which should annually be expended in gold or silver medals, or the like, to be openly awarded to youthful chemists who shall produce the best original memoirs on that branch of science dear to our deceased friend, the medals, in their style and impress, commemorating his worth as well as the investigator's merit.

I need hardly presume to say that to such a movement I should be glad to contribute my small quota of time and money, if emanating from any person more entitled to the consideration of chemists than—Your obedient servant,

B. W. GIBSON, B.Sc.

Eaton Square, S.W.
October 10th, 1870.

CHEMICAL NOTICES FROM FOREIGN SOURCES.

Under this heading will be found an encyclopaedic list of chemical papers published abroad during the past week, with abstracts of all susceptible of advantageous abridgment. The two half-yearly volumes of the CHEMICAL NEWS, with their copious indices, will, therefore, be equivalent to an English edition of the "Jahresberichte."

NOTE. All degrees of temperature are Centigrade, unless otherwise expressed.

The American Journal of Science and Arts, September, 1870.

This number opens with the announcement that a third series of this periodical, originally started in 1818, will be commenced on the 1st of January next, and the issue will then become monthly. The following original papers and memoirs relate to physico-chemical and collateral sciences:

Atomic Volumes of Solid Compounds.—F. Wigglesworth Clarke.—This lengthy memoir, full of cyphers and formulæ, winds up as follows:—Now to sum up the important relations traced in this paper, bearing in mind that, in many cases, exceptions exist:—(1) When similar metals have equal atomic volumes, those of their similar compounds will also be equal; (2) metals whose atomic volumes are unequal, but simply related to one another, often form similar compounds having equal values; (3) some compounds have atomic volumes which stand in very simple relations to the sums of those of the free elements which form them; (4) compounds formed by the union of similar elements have atomic volumes which are multiples of the lowest for that group; (5) we may add the multiple relations traced in my former papers, which not only connect the atomic volumes of different elements but the various values for each single element. May we not say, the author proceeds, that, in all compounds, the atomic volume of every element will be either a perfect multiple of the lowest value for that element, or of the lowest value in the group to which it belongs? Although this theory cannot be regarded as entirely proved, it certainly possesses a considerable degree of probability, and seems to harmonise well with the regularities which I have pointed out; but why an element should have a higher value in one compound than in another remains to be accounted for, although upon this point, perhaps, Dr. Buffa's idea, that the different degrees of quantivalence of an element in its various compounds cause the difference in its atomic volumes, may prove correct. But, at all events, whether the theory I put forward turns out true or false, it may, perhaps, by lending some sanction to the study of atomic volume, pave the way for something of greater value.

Researches in Electro-Magnetism.—Dr. A. M. Mayer.—This lengthy memoir, illustrated by a series of woodcuts, contains an exhaustive account of a series of more than thirty experiments, made with the view to ascertain the relative forces of two electro-magnetic cores—one composed of insulated wires; the other, of the same number of similar wires, uninsulated.

Precipitation and Determination of the Metals of the Magnesium Group in the form of Oxalates.—W. Gould Leison.—Reserved for reproduction in full.

New Analytical Process. J. H. Talbott.—The process alluded to is the precipitation of zinc from a neutral, or nearly neutral, solution, by the addition of soluble ammoniacal sulphide to the boiling zinc-containing solution. An excess of the precipitant is to be avoided; a white granular sulphide of zinc settles rapidly down, and is washed with hot water by Bunsen's method. The sulphide of zinc is partially dried with the filter, brought into a porcelain crucible, and ignited, at first gently, and afterwards strongly, with free access of air. The expulsion of the last traces of sulphuric acid is facilitated by the addition of small fragments of carbonate of ammonia; pure oxide of zinc at last remains. The author states that this method of quantitative estimation of zinc is very correct; manganese may be estimated by a similar process.

Quantitative Separation of Tin and Tungsten.—J. H. Talbott.—The method described by the author is based on the fact that stannic
